Hyperinsulinemia, Risk Factors, and Coronary Heart Disease
The Zutphen Elderly Study
Edith J.M. Feskens, Daan Kromhout

Abstract We investigated the association between fasting insulin concentration—an indicator of insulin resistance in nondiabetic individuals—cardiovascular risk factors, and coronary heart disease in a study of 390 men in the town of Zutphen. In 1990, an extensive examination was carried out on the participating men (aged 70 to 89 years). Fasting insulin levels were determined and a number of other risk factors measured. Known and newly diagnosed diabetics were excluded from the data analyses. Fasting insulin concentration was significantly associated with levels of glucose, triglycerides, uric acid, serum albumin, creatinine, and fibrinogen as well as resting heart rate. Inverse associations with high-density lipoprotein cholesterol and factor VII activity were observed. These results were independent of confounding factors such as age, body mass index, ratio of subscapular to triceps skinfold thicknesses, cigarette smoking, physical activity, and alcohol consumption. Men with a fasting insulin level higher than 80 pmol/L (highest quartile of the distribution) had a significantly higher prevalence of coronary heart disease and especially of myocardial infarction. This result was independent of potential confounding variables as well as of possible intermediates (total and high-density lipoprotein cholesterol, hypertension, serum triglycerides, fasting glucose, and other risk factors related to fasting insulin) (odds ratio, 2.2; 95% confidence interval, 1.2-4.0). No association between fasting insulin level and hypertension or blood pressure was observed. These results show that fasting insulin is an important indicator of coronary heart disease in elderly men. Clotting factors, resting heart rate, uric acid, serum albumin, and creatinine may also play a role in this metabolic syndrome. (Arterioscler Thromb. 1994;14:1641-1647.)

Key Words • coronary heart disease • diabetes mellitus, non-insulin-dependent • hypertension • insulin • serum lipids

It has been appreciated for a long time that a number of cardiovascular risk factors tend to cluster in the same individuals.1-7 Recently, an etiologic framework for this observation was provided by Reaven,8 who referred to this clustering as "syndrome X." The basic components of this syndrome are insulin resistance, hyperinsulinemia, hyperglycemia, dyslipidemia (notably high levels of triglycerides and low levels of high-density lipoprotein [HDL] cholesterol), and hypertension, predisposing to coronary heart disease and non-insulin-dependent diabetes mellitus (type 2). In this view, insulin resistance, hyperinsulinemia, or both are the main underlying metabolic deteriorations, and this cluster is now more frequently referred to as the insulin-resistance syndrome or multiple metabolic syndrome.8-12

However, some elements of this hypothesis remain controversial. Several epidemiological studies failed to show an association between insulin and hypertension.13-16 Only a few studies showed an association between insulin and the risk of coronary heart disease,17-19 and results varied according to the subgroup studied or the insulin measurement used.20 Other cardiovascular risk factors have also been put forward as part of the cluster.9 Finally, the extent to which the clustering of risk factors is caused by underlying associated determinants such as overweight, physical activity, smoking, and alcohol consumption is unclear.20

In 1990 an extensive examination was carried out on all members of the Zutphen Study, a longitudinal study on chronic disease risk factors. The relation of fasting insulin, an indicator of insulin resistance in nondiabetic individuals, to coronary heart disease and its risk factors, including clotting factors, was studied in this cohort of elderly men, a population generally prone to these disorders. Special attention was paid to the potential confounding effects of obesity, physical activity, cigarette smoking, and alcohol consumption.

Methods

Study Population
The Zutphen Study is a longitudinal study on chronic disease risk factors that was initiated in 1960 as the Dutch contribution to the Seven Countries Study.21-22 In 1985, 555 men of this cohort were still alive and invited for a new examination. In addition, a random sample of 2 of 3 of all other men of the same age, 65 to 84 years, and living in Zutphen was selected (n=711). This resulted in a total population of 1266 men, of which 939 (74.2%) finally took part in the survey and formed the cohort of the Zutphen Elderly Study. In the spring of 1990, 718 of these 939 men were alive and invited for participation in a new survey, of which 560 did (response rate, 76%). For the present analyses, all men with diabetes (known and newly diagnosed during the survey by oral glucose tolerance test [OGTT]) were excluded, together with 93 men with incomplete information on fasting insulin.

and confounding variables. This resulted in a study population of 389 nondiabetic men.

Examinations

The men were examined according to the protocol used in previous surveys of the Seven Countries Study. The physical examination was carried out by trained physicians from March through June 1990. Weight and height were measured with participants dressed in underwear only. Height was measured with a stadiometer and rounded to the nearest millimeter. Body weight was recorded to the nearest 0.5 kg on a calibrated scale. Body mass index was calculated from weight and height (kilograms per meter squared). Subscapular skinfold and tricipital skinfold thicknesses were measured with a Harpenden caliper in duplicate. Blood pressure was measured with the men in a supine position and the cuff on the right arm. Systolic and diastolic (fifth Korotkoff phase) pressures were recorded, and the mean value of two repeated measurements was used in the analyses. The use of antihypertensive drugs also was recorded. The presence of hypertension was defined as systolic blood pressure equal to or greater than 160 mm Hg, diastolic blood pressure equal to or greater than 95 mm Hg, or the use of antihypertensive drugs. Resting heart rate was determined from the electrocardiogram (ECG), which was taken after subjects had rested 10 minutes in a supine position. The physician asked questions regarding smoking using a standardized questionnaire.

An OGTT was carried out during a second visit of the participants to the study center. Procedures were according to guidelines of the World Health Organization. Subjects treated with insulin or oral hypoglycemic agents were excluded from the test. The first blood sample was obtained in the morning after an overnight fast. Second and third samples were obtained 1 and 2 hours after a glucose load of 75 g. Samples were collected in tubes with sodium fluoride. Plasma glucose was determined using the hexokinase method. Fasting glucose levels of 7.8 mmol/L or higher and/or 2-hour glucose levels of 11.1 mmol/L were considered as indicative of diabetes, as recommended. Insulin was measured in serum collected from subjects in a fasting state using a radioimmunoassay from Pharmacia Diagnostics. Within- and between-run coefficients of variation ranged from 6% to 7%.

Other blood samples were obtained by venipuncture after minimal stasis. Triglycerides were determined in serum collected from subjects in a fasting state of the OGTT; whereas other analyses were done on nonfasting samples obtained during another visit of the participants to the study center. Serum total and HDL cholesterol and triglycerides were determined enzymatically in citrate plasma produced by a specific medical history, ie, severe chest pain lasting for more than 20 minutes and not disappearing at rest; characteristic ECG changes (major or lesser Q waves and minor T findings); and specific enzyme elevations. Probable myocardial infarction was diagnosed when one of the three criteria was met. The diagnosis of angina pectoris was based on criteria of the questionnaire: chest pain or discomfort located at the sternum or left chest plus left arm caused by the effort of walking or hurrying, compelling the patient to slow down or take nitroglycerin, and relieved within 10 minutes after the effort was stopped.

Statistical Analyses

Statistical analyses were carried out using the SAS program (version 6.07). Since several variables were not normally distributed, Spearman's rank correlations were used to investigate bivariate and multivariate associations. Logistic regression analysis was used to investigate the association between fasting insulin and the presence of hypertension and coronary heart disease. Hyperinsulinemia was assumed for the highest quartile of fasting insulin. This cutoff point was confirmed by cluster analysis (PROC FASTCLUS on standardized values of fasting insulin), showing that 95 of the 389 men could be designated to a cluster characterized by high fasting insulin levels. For simplicity and comparative purposes, the classification according to quartiles was preferred. All probability values were based on two-sided tests of statistical significance.

Results

In spring 1990, 389 nondiabetic men aged 70 to 89 years were investigated. Mean age was 75.1 years. Fasting insulin levels in this population ranged from 21.6 to 254 pmol/L, with a median value of 60 pmol/L. Men with insulin levels higher than 80 pmol/L (highest quartile) were considered to be hyperinsulinemic. These men had significantly higher levels of body mass...

HDL indicates high-density lipoprotein.

*Fasting insulin ≥80 pmol/L.
†Adjusted for age, body mass index, subscapular-to-triceps skinfold ratio, physical activity, cigarette smoking, and alcohol consumption.

 index and a lower mean level of physical activity (Table 1). The proportion of men using alcohol and smoking cigarettes did not differ between the two groups.

Investigation of the selected metabolic risk factors found that fasting and 2-hour glucose, serum triglycerides, creatinine, albumin, and uric acid as well as diastolic blood pressure were significantly higher among men with hyperinsulinemia (Table 2). The mean level of HDL cholesterol was 0.17 mmol/L lower compared with men without hyperinsulinemia (P<.001).

Fasting insulin levels were significantly associated with fasting and 2-hour glucose levels, serum triglycerides, uric acid, albumin, creatinine, diastolic blood pressure, and resting heart rate, whereas significant inverse associations were observed with HDL cholesterol and factor VII activity (Table 2). After adjustment for potential confounding variables such as age, body mass index, subscapular-to-triceps skinfold ratio, physical activity, cigarette smoking, and alcohol consumption, the associations remained statistically significant except for the association with diastolic blood pressure, which disappeared. The adjusted association between fasting insulin and fibrinogen reached statistical significance. When adjustments were made for socioeconomic status, 2-hour glucose levels, presence of coronary heart disease, or use of antihypertensive medication (mostly diuretics or β-blockers), the correlation coefficients remained essentially the same.

No independent association between hyperinsulinemia and blood pressure levels was observed. Twelve percent of the men used antihypertensive drugs. The overall prevalence of hypertension (systolic blood pressure ≥160 mm Hg and/or diastolic blood pressure ≥95 mm Hg or use of antihypertensive drugs) was 38.5% and amounted to 45.8% among the highest quartile of fasting insulin and 36.4% among the other men. The odds ratio was 1.44 (95% confidence interval [CI], 1.33-4.47). Additional adjustments for socioeconomic status or presence of coronary heart disease or exclusion of men using antihypertensive drugs did not appreciably alter this result. When the association was investigated among men with a body mass index less than 27 kg/m² and normal glucose tolerance, the odds ratio was reduced to 1.10 (95% CI, 0.50-2.39).

The prevalence of coronary heart disease amounted to 25.3% and was significantly higher among men with the highest insulin levels (Table 3). After adjustment for potential confounders, the odds ratio amounted to 2.8, whereas after additional adjustments for all related cardiovascular disease risk factors, the odds ratio was 2.4 (95% CI, 1.33-4.47). Additional adjustments for other factors such as socioeconomic status or use of antihypertensive medication resulted in similar effect estimates. When the different components of coronary heart disease were investigated separately, the strongest associations were found for definite and probable myocardial infarction (Table 3). For angina pectoris, no significant association with hyperinsulinemia was ob-

Discussion

The results of our study show that fasting insulin is an important indicator of coronary heart disease prevalence in the elderly independent of potential confounding variables such as body mass index, physical activity, alcohol consumption, and cigarette smoking. In addition, whereas hyperinsulinemia was associated with postload glucose, dyslipidemia, resting heart rate, fibrinogen, factor VII, uric acid, serum albumin, and serum creatinine, these metabolic intermediates could not account for the relation with coronary heart disease.

Among nondiabetics, fasting insulin is an indicator of insulin resistance,35,36 and thus our results can be interpreted as associations with the insulin-resistant state. The full effect of insulin resistance on coronary heart disease may even be underestimated to some extent because we excluded men with diabetes from our analyses. Insulin was measured with a conventional immunoassay known to cross-react with proinsulin. Proinsulin levels are increased in diabetics and subjects with impaired glucose tolerance,37 and some authors argue that this causes a false observation of an association between hyperinsulinemia and glucose tolerance. However, when proinsulin is taken into account, subjects with impaired glucose tolerance are still shown to have increased insulin concentrations.36 In fact, proinsulin constitutes only a minor part of the total insulin measured by the assay and thus cannot account for our observations.

Our study population consisted of elderly men. Elderly subjects are in general prone to diabetes and glucose intolerance as well as to cardiovascular diseases and therefore form an appropriate study population for the investigation of the hypothesis of the insulin-resistance syndrome. This is confirmed by the high prevalence of the syndrome as indicated by our cluster analysis (25%) and the high prevalence of the combination of one or more risk factors in the men with hyperinsulinemia. Theoretically, it is possible that selective mortality would have favored relatively mild cases of coronary heart disease to survive up to this age, having consequences for associations with risk factors.
However, associations between insulin and other risk factors such as serum lipids are as expected,4,7 and therefore the results are unlikely to be biased.

Insulin was strongly associated with dyslipidemia, notably with increasing levels of triglycerides and decreasing levels of HDL cholesterol. This has been observed by others,4,7 and recently Haffner and coworkers12 confirmed this association in a prospective study: subjects with hyperinsulinemia had the highest risk of developing hypertriglyceridemia and low HDL cholesterol levels after 8 years of follow-up and also after adjustment for overweight and body fat distribution. Several mechanisms for this observation have been suggested,6–9 such as an increased very-low-density lipoprotein (VLDL) production by increased availability of free fatty acids, a reduced VLDL clearance, or reduced adipose tissue lipoprotein lipase activity. Theoretically, impaired insulin action may also be a result of increased VLDL triglycerides or free fatty acids, described as the Randle cycle.6,8

No association between hyperinsulinemia and total cholesterol was observed. This has also been confirmed by others, although in some studies weak positive associations were noticed.38,39 In our earlier longitudinal study, changes in glucose tolerance were independently associated with changes in total cholesterol, suggesting an association with insulin resistance.9 However, this could also have been due to underlying changes in common determinants, such as fat intake,9 and this issue requires further study.

Fasting insulin tended to be associated with blood pressure and the prevalence of hypertension, but the results were not statistically significant. Insulin resistance has been found among lean hypertensive individuals in a number of studies.8,9,40 Several mechanisms have been proposed to explain this observation, including effects on renal sodium absorption, cation transport, proliferation of vascular smooth muscle cells, and effects on the sympathetic nervous system.9 Also, confounding effects caused by the use of antihypertensive medication such as diuretics or β-blockers could play a role.41 However, epidemiological population-based studies have until now produced conflicting results. Modan and coworkers2 observed an association between postload insulin levels and hypertension independent of body mass index, glucose intolerance, age, and antihypertensive medication. In contrast, studies such as on US elderly of the Rancho Bernardo Study13 and the Baltimore Study of Aging16 and among populations in the Pacific region14 failed to confirm this observation. The association between fasting insulin and diastolic blood pressure in our study was borderline significant but disappeared after adjustment for body mass index. A similar phenomenon was noticed in the prospective study on Mexican Americans by Haffner and coworkers,12 in which after adjustment for overweight the odds ratio decreased from 1.9 to 1.5. Confining the analyses to lean individuals, similar to studies carried out in patients,8,9,40 resulted in identical findings.

Although insulin was not independently related to blood pressure levels, additional evidence for an association with systemic activity or hyperdynamic circulation can be derived from our observation of an independent association between fasting insulin and resting heart rate. This finding is in line with our previous observation that resting heart rate is an independent predictive factor for the 25-year risk of diabetes mellitus in middle-aged men.3 Also, in the San Antonio Heart Study a relation between insulin levels and heart rate was observed.42

High serum creatinine levels are indicators of renal failure and as such are of interest in the insulin-resistance syndrome with respect to diabetic complications such as nephropathy, as well as with respect to their association with hypertension.43 In our study the fasting insulin level was independently associated with serum creatinine, and this could provide additional evidence for an existing relation between insulin resistance and hypertension. Additional analyses showed that factors such as meat intake and hematocrit did not confound the association. However, it should be noted that serum creatinine also depends on muscle creatinine production and that it is not clear to what extent hyperinsulinemia or other confounding factors are related to this process.

Uric acid was another positive correlate of insulin independent of body mass index and skinfold ratio. Additional analyses showed that the correlation coefficient was not affected when potential common underlying determinants such as fat or protein intake44 were taken into account. Uric acid is well known to be associated with overweight and body fat distribution. However, in several studies uric acid was observed to be predictive of the risk of diabetes, independent of body mass index,45,46 and independently associated with insulin resistance as measured in 37 nondiabetic subjects with the euglycemic clamp technique.47 Since the subscapular-to-tricipital skinfold ratio was used as an indicator of fat distribution over the body instead of the waist-to-hip ratio, which was not available in this study, some residual confounding with respect to body fat distribution may still exist. However, the correlation coefficient was relatively large, indicative of a true phenomenon. As for the relation between insulin and serum creatinine, a possible explanation may be related to an early defect in renal clearance.48

We also observed a positive, albeit weak, association between fasting insulin and serum albumin independent of age and overweight or presence of coronary heart disease or hematocrit. Little is known about the relation between serum albumin and chronic disease. Recently, Hu and coworkers49 reported an association between serum albumin and blood pressure independent of serum calcium, hematocrit, and antihypertensive drug use. The authors postulated that this could be related to a blood pressure-lowering effect of tryptophan, the only amino acid binding noncovalently to serum albumin.50 However, vascular permeability, and thus possibly intravascular volume, has been associated with serum albumin concentrations.49,51 Although the associations between insulin and albumin and between albumin and blood pressure remain to be confirmed by others, they suggest that some biological relations between these metabolic and vascular factors exist.

In addition to well-known associated factors such as serum lipids and blood pressure, insulin was shown to be independently associated with other cardiovascular risk factors such as fibrinogen and factor VII in our study. This suggests that the clotting system is involved in the insulin-resistance syndrome. Several studies have
shown that fibrinogen is a risk factor for coronary heart disease and cerebrovascular accident. Barker and coworkers observed increased levels of fibrinogen and factor VII among individuals with syndrome X. For fibrinogen, the results of our study point in the same direction, providing further evidence for an important link between metabolic risk factors and thrombogenesis.

On the basis of former studies indicating a positive association between serum triglycerides and factor VII activity, factor VII was expected to increase with increasing insulin levels. In contrast, an inverse relation was observed independent of other risk factors and prevalence of coronary heart disease. This may be due to confounding by underlying determinants, although additional analyses showed that they could not be explained by, for instance, differential associations with dietary factors such as fat intake or by the presence of cardiovascular disorders or the use of anticoagulants. Methodological aspects may have played a role, such as cold activation during the preparation of plasma, but it is not clear to what extent this may have affected our results. This issue remains to be explored in further studies.

Besides associations with cardiovascular disease risk factors, we showed that fasting insulin level was significantly related to the prevalence of coronary heart disease and especially the presence of myocardial infarction. This relation could not be explained by factors such as age, overweight, fat distribution, physical activity, alcohol use, and cigarette smoking nor by associated biological risk factors such as dyslipidemia, hypertension, hemodynamic activity, and clotting factors. This suggests that these variables do not mediate the relation. Thus, other explanations should be considered. It has been suggested that insulin and glucose may have a direct atherogenic effect. The process could also be mediated by other unmeasured risk factors, such as tissue plasminogen activator and plasminogen activator 1 activity, low-density lipoprotein subclass, or modified (glycosylated) low-density lipoprotein. Common underlying genetic determinants also could be involved. Since the present study is of a cross-sectional nature, it cannot be excluded that insulin levels are increased because of the presence of coronary heart disease, because it is well established that glucose tolerance deteriorates directly after an infarction. However, this usually is a temporary phenomenon, and it is unlikely that this has played a major role in the present situation because most of the men had their myocardial infarction several years before the survey.

Until now, three prospective studies have shown that insulin is an independent risk factor for coronary heart disease. Prospective studies in the elderly are scarce, and the association between fasting insulin and incidence of coronary heart disease was weak and not independent of the presence of diabetes in a study among Swedish elderly men. However, Mykkänen and coworkers observed an independent association between insulin and angina pectoris and ischemic ECG changes in elderly men and women. Together with our findings of associations of insulin with other important biological risk factors and myocardial infarction in elderly men, this demonstrates that the insulin-resistance syndrome, including coronary heart disease, is present in older age groups, and prevention seems warranted.

Acknowledgments

This study was supported by a grant from the Netherlands "Praventie Fonds," The Hague, Netherlands. We are indebted to the fieldwork team in Zutphen, especially to Bennie P.M. Bloemendal, for coordinating the survey, and to Dr E.B. Bosschieter; to the Laboratory of Clinical Chemistry and Haematology of the Nieuw Spitaal Hospital in Zutphen (Dr K. Jaspers and A. Hulme); to the Laboratory of the Unit of Teratology, Endocrinology and Perinatal Screening of the RIVM (Dr J.G. Loepfer and L. Elvers) for the analyses of serum insulin; and to the Laboratory of the Department of Human Biology, University of Limburg in Maastricht (Dr G. Hornstra, P. Muller, and Dr R. Mensink), for analyses of clotting factors.
