Complex Association of Protein C Gene Promoter Polymorphism With Circulating Protein C Levels and Thrombotic Risk

Martine Aiach, Viviane Nicaud, Martine Alhenc-Gelas, Sophie Gandrille, Emmanuel Arnaud, Jean Amiral, Louis Guize, Jean-Noël Fiessinger, Joseph Emmerich

Abstract—The allele and haplotype frequency of the –1654 C/T and –1641 A/G protein C (PC) gene promoter polymorphisms was determined and analyzed according to circulating PC concentrations in 394 healthy subjects aged 20 to 60 years. The CG haplotype was associated with a lower PC concentration in both homozygous and heterozygous subjects compared with noncarriers. The TA allele had the reverse effect, but only in homozygotes. The distribution of the CG and TA alleles was significantly different in 242 patients, aged 17 to 60 years, with venous thromboembolism. The CG allele increased the risk of thrombosis, with an OR of 1.39 (95% confidence interval (CI), 1.04 to 1.87). The TA allele was also significantly associated with older age at the first thrombosis. This study confirms the link between the PC gene promoter and circulating PC levels, and suggests a complex effect on the risk of thrombosis. (Arterioscler Thromb Vasc Biol. 1999;19:1573-1576.)

Key Words: thrombosis ■ protein C ■ promoter ■ genetic risk

The protein C (PC)–protein S (PS) system is one of the most important mechanisms downregulating blood coagulation. PC is a vitamin K–dependent zymogen activated by the thrombin–thrombomodulin complex at the surface of endothelial cells. Activated PC forms a complex with its cofactor PS, and proteolytically inactivates activated factor V and factor VIIIa.

Hereditary PC deficiency was first identified in subjects who had about half of the normal PC concentration and a family history of thrombosis. In many families, a PC gene abnormality cosegregates with PC deficiency and with a thrombotic phenotype. The thrombotic risk associated with low PC concentrations was confirmed in the Leiden thrombophilia study, and individuals with the homozygous CGT genotype were found to have a 50% to 100% greater risk of venous thrombosis than individuals with the homozygous TAA genotype. The limitation of this study was that only CGT and TAA homozygotes were precisely genotyped.

The present study was designed to determine the genotype and allele frequencies of these polymorphisms in a large population, to identify a link with the PC concentration in normal subjects, and, if the effect of the polymorphisms on PC gene expression was confirmed, to seek a link with the risk of thrombosis. According to Scope, the transcriptional efficiency of these haplotypes is driven by the polymorphisms at positions –1654 and –1641. We thus used a method that allowed the C/T and A/G haplotype (theoretically CG, CA, TA, and TG) to be determined on an amplified fragment encompassing both the –1654 and –1641 polymorphic sites. The frequency of the PC promoter haplotypes...
and their different combinations were determined in 394 control subjects and 242 patients with DVT.

Methods

Subjects
Healthy subjects, aged 20 to 60 years, were recruited between May and September 1996 from a health care center to which they had been referred for a routine checkup. None of these subjects had a history of arterial disease (stroke, myocardial infarction, angina, or peripheral vascular disease), venous thrombosis (pulmonary embolism or DVT), or known malignancy, as reported on a medical questionnaire.

Patients with venous thromboembolism (VTE) were recruited from the vascular medicine unit of a Paris hospital from November 1995 to June 1998 and were enrolled onto the study if they were younger than 61 and had experienced at least 1 episode of objectively diagnosed DVT (ultrasound sonography or venography) and/or pulmonary embolism (perfusion and ventilation lung scan, conventional pulmonary angiography, or computed tomographic angiography). Blood sampling for DNA analysis, demographic data, and clinical characteristics recording were performed at the time of inclusion. The study was approved by the local ethics committee and all the subjects gave their informed consent.

Laboratory Investigations
Venous blood was collected onto 0.129 M trisodium citrate (1:10) and plasma was kept frozen until use.

PCantigen (PCag) was assayed by an immunoenzymatic method (Asserachrom Protein C, Diagnostica Stago). Control plasma was assayed within 3 months using a pool of plasma from 50 healthy men, aged 20 to 60, to construct the reference curve.

Molecular Biology
The PC gene promoter was analyzed after polymerase chain reaction amplification of the fragment of the promoter encompassing nucleotides –1738 to –1596 in the numbering system of Foster et al.9 Denaturing gradient gel electrophoresis (DGGE) of the amplified fragments was performed as described elsewhere.13 Using this method, the haplotypes (CG, CA, TA, and TG) resulting from combinations of the 2 polymorphic sites (–1654 and –1641) can easily be determined. However, we never encountered the TG haplotype in a genotyping study of >1000 subjects.

The factor V Arg506Gln mutation was identified using a previously described method.14

Statistical Analysis
Data were analyzed using the SAS statistical software (SAS Institute Inc). Hardy-Weinberg equilibrium was tested by a χ² test with 2 degrees of freedom (df) separately in cases and controls. Allele frequencies were deduced from the genotype frequency.

The level of PCag was studied in controls according to genotypes. The CG and TA genotypes were each studied as a biallelic polymorphism by reference to CA-CA carriers: homozygotes (CG-CG or TA-TA), heterozygotes (CG+ or TA+), and noncarriers. Both CG and TA genotypes (2 df each) were entered into a linear model (PROC GLM) with the dependent variable being PCag, adjusting for age and sex.

The ORs for DVT associated with 1 copy of CG and TA were calculated by a logistic regression procedure (SAS-PROC LOGIST), where both genotypes were entered together. CG and TA were coded as 2-ordered variables with 1 df, assuming additive effects of alleles (ie, tested as continuous): 0, noncarriers; 1, heterozygotes for CG or TA, respectively; 2, homozygotes for CG or TA, respectively. Thus the ORs are for 1 copy of the CG or TA allele. The log-likelihood of this model was not significantly different from that of a model where the genotypes were coded as 2 dummy-variables, contrasting the effect of heterozygotes and homozygotes to noncarriers (equivalent to single variables with 3 unordered categories, assuming no particular genetic model).

The recurrence of thrombosis, associated pulmonary embolism, and VTE associated with acquired risk factors (pooling contraception, pregnancy, surgery, prolonged immobilization, or cancer) according to genotype was tested in cases by a χ² test.

The difference in age at first thrombosis was tested by a general linear model adjusted for sex, where both CG and TA genotypes were entered.

The homogeneity of the results in men and women, and across age, was systematically tested by entering the corresponding interaction term. P<0.05 was considered significant.

Results
Table 1 shows the characteristics of the study population. Cases and controls were well-matched in terms of sex and age. As expected, the factor V Arg506Gln mutation was observed in 19.5% of cases and 3.8% of controls (P<0.001). Women on oral contraception (a known risk factor for DVT) were more frequent among cases than among controls. The occurrence of thrombosis was associated with a known acquired risk factor in 59.5% of the cases. VTE was recurrent in 27.5% of the cases, and 40.1% of the cases had pulmonary embolism.

The distribution of the PC gene promoter CG/TA/CA genotypes in the 394 controls is shown in Table 2. There was no significant deviation from Hardy-Weinberg equilibrium in the controls. CG was the most frequent allele and CA the least frequent.

Difference in allele distribution between cases and controls P=0.012
The clinical circumstances of the thromboses were then analyzed according to the PC promoter genotype. We observed an effect of the TA allele on age at the first thrombosis, which occurred at a mean (adjusted for sex) of 36.4 years in noncarriers, 38.8 years in heterozygotes and 44.2 years in homozygotes ($P=0.07$; assuming an additive effect of alleles, $P=0.03$). The CG allele had no such effect on age at onset.

The presence of acquired risk factors for thrombosis was also analyzed in CG and TA carriers. The CG allele was not significantly related to the type of thrombosis (spontaneous or acquired). In the younger patients (<45), acquired risk factors were less frequent among TA carriers: 57% in carriers versus 79% in noncarriers ($P=0.008$, 1 df). This effect, suggesting a protective effect of TA on development of thrombosis associated with acquired risk factors, was not observed in patients >45 years old.

No link was found between PC gene promoter polymorphism and the recurrence of thrombosis.

### Discussion

We took advantage of the proximity of 2 frequent polymorphisms of the PC gene promoter to determine haplotypes with the DGGE technique in 636 subjects from Paris. Three hundred ninety-four of these subjects, aged 20 to 60 years, were recruited in a health center if they reported no history of venous or arterial thrombosis. Two hundred forty-two patients, aged 17 to 60 years, with confirmed VTE were recruited in a hospital vascular medicine unit. The controls and cases all lived in the Paris area, but there were no geographic or ethnic criteria for eligibility. It was thus important to check that the 2 populations were comparable with other European populations in terms of genetic risk factors for thrombosis. The frequency of the factor V mutation was 19.5% in the patients with thrombosis (cases) and 3.8% in the subjects without thrombosis (controls). These frequencies are similar to those observed in other studies. The distribution of the prothrombin 20210A allele (10.2% versus 2.8% in cases and controls, respectively), which has been found to increase the risk of venous thrombosis, was also similar to that seen in other European populations.

The respective frequencies of the CG, TA, and CA alleles were 39.8%, 36.3%, and 23.9% in our 394 French controls; 35.3%, 28.4%, and 32.4% in 88 Dutch subjects. The CG and TA alleles were thus slightly more frequent in our population, whereas the CA allele was less frequent. It is noteworthy that we never found the TG haplotype in the 636 subjects tested, whereas 3.9% and 4.5% of British and Dutch subjects, respectively, had this haplotype. The PC concentration was measured in the 394 controls using an immunoenzymatic assay, and the results confirmed the effect of the CG and TA alleles on PC gene expression. This effect had initially been established by comparing 40 individuals homozygous for the CG genotype to 28 individuals homozygous for the TA genotype. The results presented here show that not only homozygous individuals, but also heterozygous individuals, for the CG haplotype have lower PC concentrations than individuals who do not carry CG. Conversely, the TA haplotype increased the PC concentration, but only in homozygotes. As the risk of venous thrombosis correlates negatively with the PC concentration, a detrimer-
Ce to confirm the link between the
ities overwhelming the apparent protective effect of the TA
and thrombosis might thus have unknown genetic abnormal-
contraception, and pregnancy. The patients with the
with acquired risk factors suggests that it interacts with risk
frequent in patients with spontaneous thrombosis than in
illustrates the complexity of the genetic factors involved in
the risk of venous thrombosis.
