Associations of C-Reactive Protein With Measures of Obesity, Insulin Resistance, and Subclinical Atherosclerosis in Healthy, Middle-Aged Women

Abstract—Obesity, the insulin resistance syndrome, and atherosclerosis are closely linked and may all be determinants of an increased acute-phase response. In this study, we examined the relationship of C-reactive protein (CRP) with measures of obesity, variables of the insulin resistance syndrome, and intima-media thickness of the common carotid arteries in 186 healthy, middle-aged women selected from the general population. Associations were assessed by regression analysis. CRP was strongly associated with body mass index (BMI) and waist circumference. CRP was also associated with other variables of the insulin resistance syndrome, including blood pressure, insulin, high density lipoprotein cholesterol, triglycerides, apolipoprotein A1 (inversely), plasminogen activator inhibitor-1 antigen, and tissue-type plasminogen activator antigen. Associations between CRP and the variables of the insulin resistance syndrome disappeared after controlling for BMI but remained significant for plasminogen activator inhibitor-1 antigen only. The association of CRP with common carotid artery intima-media thickness was weak and limited to ever-smokers. BMI explained 29.7% of the variance of CRP, whereas common carotid artery intima-media thickness explained only 3.7%. The results of this population-based study indicate that adiposity is strongly associated with CRP in healthy, middle-aged women. In this population, BMI accounted for the relationship between CRP and other variables of the insulin resistance syndrome. Further studies should determine whether losing weight ameliorates the inflammatory state. (Arterioscler Thromb Vasc Biol. 1999;19:1986-1991.)

Key Words: C-reactive protein □ obesity □ insulin resistance □ carotid artery intima-media thickness □ women

Recent data suggest that inflammation is involved in atherogenesis.1,2 C-reactive protein (CRP), a major acute-phase protein, has been associated with the presence and severity of atherosclerosis3 and has been found to predict cardiac events in subjects with4–6 and without7–9 prevalent cardiovascular disease. Raised concentrations of inflammatory mediators may reflect inflammation in the arterial wall associated with atherosclerosis but may also be causally involved in the disease process.10,11 Sources of inflammation include infections10–12 and smoking.13 Moreover, levels of obesity have been shown to be associated with low-grade inflammation.14,15

Recent data also indicate that the insulin resistance syndrome is accompanied by an increased acute-phase response.16,17 A link between the insulin resistance syndrome and the inflammatory state is further suggested by increased levels of the acute-phase proteins plasminogen activator inhibitor-1 (PAI-1) and fibrinogen in the insulin resistance syndrome18–20 and by the finding that dyslipidemia in the insulin resistance syndrome and during the acute-phase response shows strong similarities.21–23

Obesity, the insulin resistance syndrome, and atherosclerotic disease are closely linked and may all be determinants of an increased acute-phase response. However, it is not clear whether these factors are independently associated with the inflammatory state. Previous studies on associations between CRP level as a measure of inflammation and cardiovascular risk factors were conducted in middle-aged men and elderly men and women, all of whom are at relatively high risk for atherosclerosis.14,15 Atherosclerosis and smoking are potential sources of inflammation and possibly obscure the relation of CRP with other risk factors.

In the present study, we investigated the relationship between CRP and measures of obesity, the insulin resistance syndrome, and subclinical atherosclerosis in a population of healthy, middle-aged women with a low exposure to tobacco smoke.

Methods

Study Population

We studied a population of 186 women, aged 43 to 55 years, selected from the general population and participating in a study on the...
cardiovascular effects of natural menopause. Women were selected from respondents to a mailed questionnaire about menopause, which was sent to all women aged 40 to 60 years living in the town of Zoetermeer, the Netherlands (N=12,675). Women were considered premenopausal if they had experienced 1 or more regular bleeding episodes in the past 12 months and were free from climacteric symptoms, defined as perspiration and/or hot flushes. Women were considered postmenopausal if their menses had ceased naturally for at least 12 months. Exclusion criteria were diabetes mellitus, prevalent cardiovascular disease, and use of antihypertensive medication or cholesterol-lowering drugs. Women reporting use of female hormones (hormone replacement therapy or oral contraceptives) within 6 months before the clinical examination were excluded, as were subjects currently smoking 5 or more cigarettes per day. Of the eligible subjects, 93 premenopausal and 93 postmenopausal age-matched women were selected (response rate 76% of eligible and invited women). All women gave written informed consent, and the study was approved by the medical ethics committee of the Erasmus University Medical School.

Measurements
During a visit at the research center, a medical history was taken by a physician. Height, weight, and waist and hip circumferences were measured while the subjects wore indoor clothes without shoes. Body mass index (BMI, weight divided by height squared) and waist-to-hip ratio (WHR) were computed. Cigarette smoking history was obtained by a standardized questionnaire. Blood pressure was assessed with a Dinamap automatic blood pressure recorder (Critikon, Inc). After a 5-minutes rest in the supine position, blood pressure was measured 4 times at the right upper arm with an appropriately sized cuff, and the mean was used in the analyses. Venous blood samples were drawn from each subject after a 12-hour fast. The samples were stored at ~80°C. Total cholesterol was measured with an automated enzymatic method using the CHOD-PAP high-performance reagent kit from Boehringer Mannheim. HDL cholesterol was measured by the phosphotungstate method. LDL cholesterol was computed by the Friedewald formula. Triglycerides were determined by using a reagent kit from Boehringer Mannheim after enzymatic hydrolysis of the triglycerides and subsequent determination of liberated glycerol by colorimetry. No correction was made for serum free glycerol. Apolipoproteins A1 and B were measured by an automated turbidimetric immunoassay with reagent kits from Orion Diagnostics. Glucose was enzymatically determined by the hexokinase method (Instruchemie). Serum insulin was determined by metric assay (Biosource Diagnostics). C-peptide, PAI-1 antigen and tissue-type plasminogen activator (tPA) antigen levels were determined by ELISA (Innotest PAI-1, Innogenetics NV, and Imulyse, Biopool, respectively). CRP was measured by an in-house ELISA with rabbit anti-CRP (Dako) as the catching and tagging antibody. Intra-assay and interassay CVs for CRP were 3.8% and 4.7%, respectively. Fasting insulin levels were used as a measure of insulin resistance. In addition, insulin sensitivity was calculated according to the formula of the homeostasis model assessment method (HOMA): insulin resistance = fasting insulin × fasting glucose/22.5.27

Common carotid artery IMT was used as a measure of insulin resistance. Intra-assay and interassay CVs for CRP were 3.8% and 4.7%, respectively. Apolipoprotein A1 and B were measured by an automated turbidimetric immunoassay with reagent kits from Orion Diagnostics. Glucose was enzymatically determined by the hexokinase method (Instruchemie). Serum insulin was determined by metric assay (Biosource Diagnostics). C-peptide, PAI-1 antigen and tissue-type plasminogen activator (tPA) antigen levels were determined by ELISA (Innotest PAI-1, Innogenetics NV, and Imulyse, Biopool, respectively). CRP was measured by an in-house ELISA with rabbit anti-CRP (Dako) as the catching and tagging antibody. Intra-assay and interassay CVs for CRP were 3.8% and 4.7%, respectively. Fasting insulin levels were used as a measure of insulin resistance. In addition, insulin sensitivity was calculated according to the formula of the homeostasis model assessment method (HOMA): insulin resistance = fasting insulin × fasting glucose/22.5.27

Carotid Artery Intima-Media Thickness (IMT)
Common carotid artery IMT was used as an indicator of generalized atherosclerosis.28 Ultrasonography of the right common carotid artery was performed with a 7.5-MHz linear-array transducer (ATL Ultramark IV) as described in detail previously.28 For each individual, the common carotid artery IMT was determined as the average of near- and far-wall measurements. Carotid artery IMT measurements have been shown to be reproducible.90 In short, mean differences (and SDs) in far-wall IMT of the common carotid arteries between paired measurements of sonographers, readers, and visits were 0.040 mm (0.07), 0.069 mm (0.04), and 0.071 mm (0.09), respectively. The intraclass correlation coefficients were 0.63, 0.88, and 0.74, respectively. These results are in agreement with the reproducibility of IMT measurements found in other studies.14 In the present study, all measurements were conducted by 1 sonographer and 1 reader.

Characteristics of the population are described in Table 1. The strength of the associations between CRP and clinical and biochemical variables was assessed by linear regression of ln CRP on each variable separately, adjusted for age. Because the distribution of CRP was highly skewed, it was natural-log–transformed for all analyses. The difference in CRP between premenopausal and postmenopausal women adjusted for age and measures of obesity was studied with regression analysis. A probability value <0.05 (2-tailed test) was considered significant. SPSS 7.5 for Windows was used for all analyses.

Results
Characteristics of the population are described in Table 1. BMI ranged from 16.8 to 41.1 kg/m²; 42 subjects had a BMI >27 kg/m². CRP varied from 0.05 to 14.38 mg/L; 2 subjects had values >10 mg/L (10.70 and 14.38 mg/L), the cutpoint...
Controlling for WHR, on the other hand, had only a small influence on the described associations (data not shown). To evaluate whether the clustering of variables belonging to the insulin resistance syndrome might be a reflection of a general acute-phase response, associations between measures of insulin resistance (insulin and HOMA) and the other variables of the insulin resistance syndrome were adjusted for CRP. This adjustment did not modify the relation between insulin, HOMA, and the other variables (data not shown).

Measures of obesity and CRP in premenopausal and postmenopausal women separately are shown in Table 4. CRP did not differ significantly between premenopausal and postmenopausal women. Age-adjusted geometric means were 0.61 and 0.71 mg/L respectively (15% increase with menopause, 95% CI, −15% to 45%). Because menopause may be associated with changes in measures of obesity, we adjusted for these variables, which slightly influenced the results. Postmenopausal women had an age-adjusted level of cholesterol of 6.48 mmol/L versus 5.89 mmol/L in premenopausal women (10% difference; 95% CI, 5% to 14%). PAI-1 antigen increased with menopause, but the difference lacked statistical significance. In premenopausal women, the age-adjusted geometric mean of PAI-1 antigen was 52.9 ng/mL versus 61.1 ng/mL in postmenopausal women (13% increase with menopause; 95% CI, −8% to 33%). Because cholesterol and PAI-1 antigen are known to increase with menopause, these results indicate a correct selection of menopausal groups. The associations between CRP on the one hand and both measures of obesity and other variables of the insulin resistance syndrome on the other were found to be identical when examined in premenopausal and postmenopausal women separately (data not shown).

CRP was significantly associated with common carotid artery IMT. After stratification by smoking status, associations between CRP and common carotid artery IMT appeared to be present in ever-smokers only (Table 5). Common carotid artery IMT explained 3.7% of the variance of CRP after adjustment for age.

Discussion

Our results indicate that in healthy, middle-aged women, CRP is strongly associated with measures of obesity. CRP was associated with BMI and waist and hip circumferences but not with WHR after adjustment for BMI. CRP was also associated with other variables included in the insulin resistance syndrome. After controlling for BMI, however, the associations disappeared. Although in this population CRP was associated with common carotid artery IMT in ever-

---

Fasting insulin levels ranged from 18 to 232 pmol/L. Common carotid artery IMT ranged from 0.43 to 0.97 mm.

CRP was significantly associated with measures of obesity: BMI, waist and hip circumferences, and WHR (Table 2). Associations with CRP were stronger for BMI and waist and hip circumferences than for WHR (\( r=0.54 \) for BMI, \( r=0.55 \) for waist circumference, \( r=0.53 \) for hip circumference, and \( r=0.33 \) for WHR, all adjusted for age). After adjustment for BMI, hip circumference and WHR were no longer associated with CRP, whereas waist circumference still was. We next visualized this relationship between BMI, WHR, and CRP by subdividing the study population by the median BMI (23.9 kg/m²) and WHR (0.77) (the Figure, geometric means). BMI explained 29.7% of the variance of CRP; waist circumference, 31.3%; hip circumference, 28.7%; and WHR, 11.4%, after adjustment for age.

The other variables included in or associated with the insulin resistance syndrome were also significantly associated with CRP: blood pressure, insulin, HDL cholesterol, triglycerides, apolipoprotein A1 (inversely), PAI-1 antigen, and tPA antigen (Table 3). No associations were found with glucose or variables of the insulin resistance syndrome disappeared after adjustment for age. After controlling for CRP, variables of the insulin resistance syndrome might be a reflection of a general acute-phase response, associations between measures of insulin resistance syndrome (insulin and HOMA) and the other variables of the insulin resistance syndrome were adjusted for CRP.

smokers, measures of obesity explained a much larger part of the variance of CRP than did carotid artery IMT.

One hypothesis explaining these results is that adipose tissue might be the common antecedent of both CRP and insulin resistance. The associations between CRP and variables of the insulin resistance syndrome may thus be due to the association of BMI with both insulin resistance and the acute-phase response. This idea is consistent with experimental evidence indicating that adipocytes produce tumor necrosis factor (TNF)-α.33 TNF-α induces interleukin-6 (IL-6) synthesis, 34 a prime regulator of CRP synthesis. 35,36 Additional support for this hypothesis comes from the observation that weight reduction leads to a decrease of TNF-α mRNA expression 37 and of serum levels of TNF-α in diabetic subjects.38 We found that CRP was strongly related to BMI and to waist and hip circumferences separately, but less to WHR. These results are compatible with previous studies, in which BMI but not WHR was related to TNF-α expression or TNF-α levels.33,39 However, after adjustment for BMI, waist circumference was still related to CRP, whereas hip circumference was not. This suggests that abdominal fat deposition is most important in inducing inflammation.

Associations between CRP concentrations and fasting serum insulin concentrations, which persisted after adjustment for BMI, have been observed in a population of male patients with angina pectoris.18 In addition, in healthy, middle-aged men, relationships between CRP and cardiovascular risk factors like HDL cholesterol and triglycerides persisted after adjustment for BMI.14 One possible explanation for these discrepant results might be that the relationships between obesity, the insulin resistance syndrome, and the acute-phase response are different between men and women. Support for this hypothesis comes from the observation that sex steroids influence the metabolic activity of adipose tissue.40

‡Adjusted for age and BMI.
ally, the described studies differ from ours in that those subjects were likely to suffer from more pronounced atherosclerosis because they were male or suffering from angina pectoris. Atherosclerosis might have spuriously induced the relation between CRP and other cardiovascular risk factors. Because in our population women had a low burden of atherosclerosis, as estimated from carotid artery IMT, the potential for confounding by atherosclerosis in our study is less likely.

Associations between measures of insulin resistance and other variables included in the insulin resistance syndrome were not attenuated by adjusting for CRP levels. Therefore, our data do not suggest that the clustering of variables belonging to the insulin resistance syndrome might be a reflection of a general acute-phase response.16 Also, because the association between insulin resistance and measures of obesity was not affected by adjustment for CRP, our data do not support the hypothesis that adipose-tissue–derived cytokines may mediate the relation between obesity and the insulin resistance syndrome.17,33,37,39 However, this hypothesis encompasses a causal role for TNF-α; therefore, this inference might have been more valid had we adjusted for TNF-α instead of CRP.

The selection of premenopausal and postmenopausal women is likely to be accurate, as reflected by an age-adjusted increase of cholesterol of 10%, which is in agreement with other studies.41,42 We did not find a clear influence of menopause on CRP levels. Both age- and age-and-BMI–adjusted levels of CRP were slightly higher in postmenopausal (0.71 mg/L) than in premenopausal (0.61 mg/L) women, but this 15% difference was not statistically significant. This result can probably be attributed to the large variation of this measure. To the best of our knowledge, no published data on the association between menopause and CRP levels are available from other studies. Estrogen replacement therapy in postmenopausal women has been shown to lower TNF-α43 and acute-phase reactants other than CRP.44 Experimental data suggest an inhibitory effect of estrogens on IL-6 gene expression.45 Recent data from the Cardiovascular Health Study, however, suggest an increase of CRP with hormone replacement therapy.46 Further studies are needed to address the association between inflammation, estrogens, and menopause.

We are the first to describe an association between CRP and common carotid artery IMT in healthy, middle-aged women, which association was limited to ever-smokers (Table 4). In a study by Tracy et al15 in a population of elderly men and women, CRP was not related to internal carotid wall thickness but was related to ankle-arm index in ever-smokers only. Data from the MRFIT (Multiple Risk Factor Intervention Trial) study also show a stronger association of CRP with coronary heart disease deaths in middle-aged male smokers than in nonsmokers, as defined at baseline.8 Taken together, these and the present data suggest that CRP may mark permanent, underlying vascular damage due in part to smoking. This may explain why the associations between inflammation and atherosclerosis are more pronounced not only in current but also in former smokers. In the Physicians’ Health Study, however, smoking did not modify the relation between CRP and the risk of cardiovascular events.7

Some issues of our study need to be addressed. First, we did not measure exposure to infectious agents such as Helicobacter pylori and Chlamydia pneumoniae, which may be weak determinants of CRP levels.12,17 However, it appears unlikely that exposure to these agents would confound the association between BMI and CRP level. Second, in this study we measured atherosclerosis at only 1 location in the vascular system. Although we assume that common carotid artery IMT is a measure of generalized atherosclerosis,28 assessment of the degree of atherosclerosis might have been more accurate had we used measurements at multiple locations. Finally, this study was conducted in healthy, middle-aged women without clinical cardiovascular disease, no medication use, and a low, current exposure to tobacco. Smoking and atherosclerosis are potential determinants of CRP, and therefore, the choice of our population facilitates the investigation of other factors associated with CRP. However, in this population, ever-smoking was also found to modify the association between CRP and atherosclerosis.

In summary, our results indicate that adipose tissue is strongly associated with CRP in healthy, middle-aged women. In this population with a low burden of atherosclerosis and current smoking, BMI accounts for the association between CRP and variables of the insulin resistance syndrome. Because inflammatory mediators may be directly involved in atherogenesis, these results suggest an important mechanism through which obesity might affect the risk of coronary heart disease. Further studies should determine whether losing weight ameliorates the inflammatory state.
