Cardiovascular Risk in Type 2 Diabetes Is Associated With Variation at the \textit{PPARG} Locus

A Go-DARTS Study

Alex S.F. Doney, Bettina Fischer, Graham Leese, Andrew D. Morris, Colin N.A. Palmer

Objective—The Pro12Ala polymorphism of \textit{PPARG} modulates risk of developing type 2 diabetes. The Ala allele has also been associated with a reduced risk of cardiovascular events. We have shown previously that the linked T allele of the C1431T polymorphism influences Ala12-associated diabetes risk and that the 2 polymorphisms have opposing associations with body weight. We therefore investigated the association of these 2 variants with cardiovascular events in people with type 2 diabetes.

Methods and Results—We performed a cohort study of 2016 individuals and used Cox proportional hazards to analyze risk of myocardial infarction or death by \textit{PPARG} Pro12Ala and C1431T genotypes, adjusting for age, sex, and smoking status. In individuals enrolled <70 years of age, the hazard for a first nonfatal event associated with the Ala12 allele was 0.21 (CI, 0.06 to 0.69; \(P = 0.01\)) and the T1431 allele 9.9 (CI, 1.90 to 51.29; \(P = 0.007\)). These opposing associations remained significant after correction for other conventional risk factors. The T1431 allele was also associated with all-cause mortality.

Conclusions—This study confirms the association of the Ala12 allele with reduced risk of myocardial infarction in a type 2 diabetic population and demonstrates that the T allele independently associates with an increased risk. (\textit{Arterioscler Thromb Vasc Biol}. 2004;24:2403-2407.)

Key Words: type 2 diabetes ■ myocardial infarction ■ \textit{PPARG} ■ polymorphism
recorded according to a standard data set and case records regularly validated by a team of dedicated research nurses. This continuously updated data set comprises the clinical information system known as DARTS (Diabetes Audit and Research in Tayside Scotland), which has been described previously.20 Blood has been collected for genetic studies from a cohort of individuals in DARTS. This genetic substudy, known as Go-DARTS, therefore consists of a free-living clinical cohort selected only on the basis of having type 2 diabetes and attending a diabetes clinic in Tayside. All subjects in Go-DARTS are of white ethnicity. Rigorous compliance with National Health Service data protection and encryption standards is maintained at all times, and the study was approved by the local research ethics committee.

At the study outset, there were a total of 2016 white individuals with type 2 diabetes in Go-DARTS. Genotyping for PPARG Pro12Ala and C1431T polymorphisms was performed using Taqman (Applied Biosystems) allelic discrimination assays as described previously.11 All individuals were followed up until a cardiovascular event (nonfatal myocardial infarction or revascularization) or death from any cause after recruitment or to the end of the study period.

Hospitalization events for a myocardial infarction were obtained from the Scottish Morbidity Register. Myocardial infarction events that did not result in hospitalization were obtained from the DARTS database based on information derived from all general practices in the region. Hence, ascertainment of events was close to 100%. Although the date-of-death data are available rapidly on DARTS, there is a delay in obtaining adjudicated cause of death centrally from the Office of the General Registrar; therefore, these data were only available on a proportion of individuals who died early in the study, and thus we chose to consider only death by any cause.

Cox proportional hazards model was used to represent the association of genotype with time to event, with the end point being nonfatal myocardial infarction, revascularization, or all-cause death. The analysis was initially performed in the entire group, that is, whether or not they had experienced a previous nonfatal event. To avoid potential problems associated with survival bias and dilution of genetic effects through the multiple events that accrue with age, we analyzed time to first event in each individual in this subgroup, and it was found that the T allele was again associated with a significantly increased risk (HR, 2.55; CI, 1.13 to 5.75), whereas the Ala allele was associated with a reduced risk that was only of borderline significance (HR, 0.43; CI, 0.18 to 0.99) and the hazard associated with either polymorphism was therefore lower (HR, 0.43; CI, 0.18 to 0.99) and the hazard associated with the T allele being lower (HR, 0.43; CI, 0.18 to 0.99) and the hazard associated with the T allele higher (HR, 4.75; CI, 1.24 to 18.25). When we analyzed time to first event in each individual in this younger cohort, excluding individuals who had experienced stroke, myocardial infarction, or revascularization before enrollment, we found a further strengthening of the observed associations (HR for the Ala allele, 0.21; CI, 0.06 to 0.69; HR T allele, 9.90; CI, 1.9 to 51.29). We then considered the combined end point of nonfatal events and all-cause death in this subgroup, and it was found that the T allele was associated with a significantly increased risk (HR, 2.55; CI, 1.13 to 5.75), whereas the Ala allele was associated with a reduced risk that was only of borderline significance (HR, 0.68; CI, 0.43 to 1.1). The interaction of the T1431 and Ala12 alleles in this group are illustrated as Kaplan–Meier plots in the Figure. In A, time to event is compared between

Corrected for sex age and smoking status.
individuals with and without the Ala12 allele while adjusting for the presence of the T1431 allele. In B, time to event is compared between individuals with and without a T1431 allele while adjusting for the presence of the Ala12 allele. In C, the combined genotypes are plotted, demonstrating that individuals possessing an Ala12 allele in the absence of a T1431 allele are relatively protected from events, whereas conversely, individuals possessing a T1431 allele in the absence of an Ala12 allele are at a relatively greater risk. When an individual possesses both alleles, his/her opposing risks cancel each other, resulting in an intermediate risk similar to possession of neither allele.

Finally, considering only all-cause death in the younger group, it was found again that the T allele was associated with an increased risk of earlier death (HR, 2.61; CI, 1.02 to 6.65); however, association of the Ala allele was considerably weakened (HR, 0.82; CI, 0.49 to 1.39). We also examined cardiovascular death using this model and observed hazards of a similar magnitude; however, this was underpowered compared with the all-cause death data because of the shorter follow-up period available for the cardiovascular death diagnosis, as detailed in the methods (data not shown). Because the majority of deaths in type 2 diabetes are of cardiovascular origin, our study was underpowered to specifically determine the role of the variants in noncardiovascular causes of death.

We then determined the extent to which the observed associations were dependent on other conventional risk factors and so repeated the analysis including smoking status, log10 mean BMI, first-recorded HDL-cholesterol, total cholesterol, log10 triglycerides, and mean arterial blood pressure. We found that with inclusion of these conventional risk factors in the model, the observed associations of genotype with outcome was modestly attenuated but remained significant (Table 2).

Discussion

We have investigated the association of the Pro12Ala and C1431T polymorphisms of PPARG on cardiovascular events in a large population of patients with type 2 diabetes. We have exploited advanced record-linkage technology developed through DARTS to enable all individuals in the cohort to be prospectively followed with a high degree of sensitivity and specificity and have confirmed a previous report that the Ala allele of Pro12Ala is associated with a reduced hazard of myocardial infarction. Furthermore, we have demonstrated that the T allele of C1431T is associated with an increased hazard and that its coexistence influences the hazard associated with the Ala allele. The potential importance of the T1431 variant as a marker for cardiovascular risk is supported by a recent case control study from Taiwan that considered this variant in isolation and demonstrated a significantly increased risk of premature myocardial infarction as well as an increased level of atherogenic oxidized low-density lipoprotein-cholesterol associated with T1431 homozygotes. Furthermore, a recent study in the Oji-Cree considered the C1431T and Pro12Ala polymorphisms and demonstrated an association of the Ala12 allele with reduced carotid intima media thickness, whereas the T1431 allele was associated with an increase in total atherosclerotic plaque volume in the carotid artery. These findings corroborate previous observations that the Ala12 and the linked T1431 are associated with opposing phenotypes. Because the T allele is silent, it is likely that these observed associations are attributable to its LD with a further common variant with functional consequences at the PPARG locus.

Indeed be true also for the Ala allele, although there is some evidence that it may have functional consequences.9

We found that the opposing hazards associated with the PPARG variants were more apparent in a younger population enrolled in the study <70 years of age, probably reflecting survival biases operating in the very elderly, together with the fact that at that at an older age, the influence of genotype on events will be attenuated. For example, the Taiwanese study was able to detect the increased myocardial infarction risk associated with the T1431 allele in individuals <50 years of age,18 and interestingly, the Ala12 variant has been shown recently to be enriched in very elderly Italian.23 These findings, together with our findings that healthy middle-aged control populations have a higher Ala12 frequency relative to the white control populations, the D/H11032 value. It would indeed be true also for the Ala allele, although there is some evidence that it may have functional consequences.9

We found that the opposing hazards associated with the PPARG variants were more apparent in a younger population enrolled in the study <70 years of age, probably reflecting survival biases operating in the very elderly, together with the fact that at that at an older age, the influence of genotype on events will be attenuated. For example, the Taiwanese study was able to detect the increased myocardial infarction risk associated with the T1431 allele in individuals <50 years old,18 and interestingly, the Ala12 variant has been shown recently to be enriched in very elderly Italians.23 These findings, together with our findings that healthy middle-aged control populations have a higher Ala12 frequency relative to children,17 support our hypothesis that common variation at PPARG is involved in the regulation of inflammation and mortality. It is likely that the stronger association observed in the group with no previous cardiovascular events before enrollment reflects the effects of an increased number of cardiovascular protective drugs prescribed to individuals with previous cardiovascular events.

Because the Ala12 and T1431 alleles are in strong LD, they often occur together in the same individual and, as we have demonstrated previously, when they occur together, they effectively cancel out their associated phenotype. This is illustrated in the Figure (C), in which the survival curves are superimposed when both alleles are absent or both present. It is for this reason that considering either allele in the model on its own resulted in only a weak and nonsignificant association with cardiovascular risk compared with including both variants in the model, in which case the presence of the opposing allele is being accounted for statistically. Another consideration when interpreting reports of these variants is that the LD between the variants differs markedly by ethnicity. In white populations, the D’ is 0.6 and the allele frequencies are almost identical, giving a similar $R^2$ and D’ value. It would appear that the frequency of the T1431 variant in Asian populations may be 10-fold higher than Ala1218 and 3-fold higher in Oji Cree,19 thus providing many more individuals who contain the T1431 variant without the Ala12 variant than would be present in the white samples, which represent the bulk of the literature. Therefore, the “cross-contamination” of association by LD will be less in these samples.

In 1 study, the T allele has also been indirectly associated with a reduced risk of angiographically defined coronary artery disease.24 Interestingly, this study did not consider the Ala allele and found that the protective advantage was mainly among the C1431T heterozygotes, with C1431 and TT homozygous individuals each having evidence of increased disease. Based on our findings, we would predict that individuals homozygous for the T allele would have increased disease because of an increased ratio of T to Ala alleles, whereas CT heterozygotes, in contrast, would be expected to have an approximately equal proportion of opposing Ala alleles and would thus be relatively protected.

To the best of our knowledge, only 1 other study has considered both of these variants on coronary artery disease in a diabetic population and found no association of these or other variants with atherosclerotic vascular disease.25 However, this was a small retrospective case control and therefore subject to bias and lack of power.

Genetic variation at PPARG has also been associated with conventional risk factors for cardiovascular disease such as body weight,11 blood pressure,12 and lipids,26 suggesting the possibility that the observed association with cardiovascular risk also may be through these mechanisms. However, the inclusion of a full range of conventional risk factors including BMI in the model resulted in only a modest reduction in the impact of the alleles, suggesting that the observed genetic association was largely independent of these. However, it should be pointed out that the patients in this population were all undergoing active management of their diabetes and cardiovascular risk factors over a mean duration of 8 years because diagnosis with diabetes and this would tend to obscure differences in these parameters because of genotype. Furthermore, measures of a particular risk factor taken at only a single point in an individual’s life span are unlikely to reflect the cumulative effect of subtle modulations in PPARY activity throughout that individual’s life and the influence this may have in turn on development of cardiovascular disease. It is also likely that PPARY has a diverse role in the pathophysiology of cardiovascular disease, possibly unrelated to conventional risk factors. This is supported by recent evidence that PPARY is involved in the regulation of inflammation and endothelial function.27

In this study, we have not addressed the influence of pharmacotherapy on the association of genotype and outcome. It has been postulated that thiazolidinediones, which are PPARY activators, and increased insulin sensitivity may reduce the risk of cardiovascular risk events,28 which raises the question whether the greater risk associated with possession of the T allele can be ameliorated with thiazolidinedione...
therapy or indeed any of the other pharmacological therapies commonly prescribed to individuals with type 2 diabetes. These interesting, although complex, pharmacogenetic questions are the subject of ongoing research.

Finally, although we have not been able in this study to define the mechanism whereby variation at PPARG is associated with cardiovascular events, our observation that the association of T1431 variant with coronary events can be followed through to all-cause death, of which as many as two thirds are vascular in origin in patients with type 2 diabetes, further underpins the potential clinical importance of this pleiotropic locus. This study therefore indicates the possible clinical importance of including genotype in discriminating between individuals with differing risk profiles for premature events to inform appropriate therapeutic intervention.

Acknowledgments

This work was funded by a grant from a local trust administered by Tenovus (Tayside). C.P. and A.M. are supported by a Scottish Higher Education Funding Council 21st century genetic health research development grant. We would like to acknowledge the many individuals involved in setting up and continuing to maintain DARTS.
