The Use of Achilles Tendon Sonography to Distinguish Familial Hypercholesterolemia from Other Genetic Dyslipidemias

Mireia Junyent, Rosa Gilabert, Daniel Zambón, Isabel Núñez, María Vela, Fernando Civeira, Miguel Pocoví, Emilio Ros

Objective—Achilles tendon (AT) xanthomas, specific for familial hypercholesterolemia (FH), may be clinically undetectable. We assessed the usefulness of AT sonography in the diagnosis of FH.

Methods and Results—Sonographic AT characteristics were evaluated in 127 subjects with FH (81 genetically ascertained), 84 familial combined hyperlipidemia, 79 polygenic hypercholesterolemia, and 88 normolipidemic controls. Abnormal echostructure (sonographic xanthoma) was noted only in FH. AT thickness was higher (P<0.001) in FH men and women compared with all of the other groups and, in FH mutation carriers but not in others, correlated positively with low-density lipoprotein cholesterol (r=0.345; P<0.001) and negatively with high-density lipoprotein cholesterol (r=−0.265, P=0.015). Thickness thresholds for the diagnosis of FH with specificity >80%, as were derived from receiver operating curves, were 5.3 and 5.7 mm in men < and >45 years, and 4.8 and 4.9 mm in women < and >50 years, respectively. In FH mutation carriers, sonographic findings increased the clinical diagnosis of xanthomas from 35 (43%) to 55 (68%). Using thresholds in validation sets of 70 genetically identified FH and 54 dyslipidemic non-FH correctly classified 80% and 88%, respectively.

Conclusion—Sonographic AT characteristics are normal in non-FH dyslipidemias. Identification of suspected FH by ultrasound using sex- and age-specific AT thickness thresholds is recommended. (Arterioscler Thromb Vasc Biol. 2005;25:2203-2208.)

Key Words: Achilles tendon ■ xanthomas ■ familial hypercholesterolemia ■ genetic dyslipidemias ■ ultrasonography

Heterozygous familial hypercholesterolemia (FH) is an autosomal-dominant inherited disorder of lipid metabolism characterized by lifelong elevation of serum cholesterol that is usually caused by defects in the low-density lipoprotein (LDL) receptor (LDLR) gene.1 Clinical features include early coronary heart disease (CHD) and tendon xanthomas because of accelerated cholesterol deposition within both vascular and extravascular tissues. Tendon xanthomas are specific for FH, and the Achilles tendon (AT) is the usual location.1–3

Xanthomas are composed of monocyte-derived foam cells resulting from intracellular accumulation of lipids and connective tissue.4 In genetically ascertained heterozygous FH, xanthomas diagnosed by physical examination begin to appear after the second decade of life5 and are found in 20% to 50% of affected adults in unselected cohorts.5–7 It is unknown why some FH subjects disclose xanthomas and others do not, even while having similar LDL cholesterol levels and sharing the same LDLR defect.5 One reason may be that physical examination has shortcomings because their clinical identification as diffuse enlargements or nodular deformities in the AT or other locations is not always easy.

When available, genetic testing may secure the etiologic diagnosis of FH.1,3 Otherwise, objective sets of clinical criteria, as defined by the United Kingdom Simon Broome Register Group,8 the United States Make Early Diagnosis to Prevent Early Death Program,9 or the Dutch Lipid Clinic Network,10 are used. These diagnostic criteria are based on pretreatment lipid values, family history, and clinical manifestations. The presence of tendon xanthomas weighs heavily in the United Kingdom and Dutch scoring systems, signifying a definite diagnosis,8,10 a reason why their identification is crucial for diagnosing FH in clinical practice. Ultrasonography, a simple, affordable, and rapid imaging technique, has been used to reproducibly assess AT thickness and improve on the clinical diagnosis of xanthomas.11–16 However, the...
ultrasound characteristics of AT in other genetic dyslipidemias disclosing elevated blood cholesterol levels that might easily lead to a suspicion of FH have not been evaluated. The aim of this study was to assess the usefulness of AT sonography to distinguish genetically ascertained FH from clinical FH without a molecular diagnosis and other genetic dyslipidemias in comparison with normolipidemic subjects.

**Methods**

**Subjects**

From March 2000 to April 2005 we evaluated 290 consecutive adults with a diagnosis of primary hypercholesterolemia attending the Lipid Clinic of Hospital Clinic, Barcelona. Depending on family history, physical signs, and lipid levels, subjects were given a clinical diagnosis of FH, familial combined hyperlipidemia (FCH), or polygenic hypercholesterolemia (Table 1). Subjects were referred for diagnosis or because of refractoriness to treatment, and they had no polygenic hypercholesterolemia (Table 1). Xanthomas were searched at the usual locations (4 knuckles, 2 elbows, and 1 pretibial). Family history of premature CHD, and absence of apo E 2/2 genotype.

**Clinical and Laboratory Characteristics**

All of the subjects were assessed for standard cardiovascular risk factors (Table 1). Xanthomas were searched at the usual locations (dorsum of the hands, elbows, pretilib tuberosities, and AT) by the same physicians (D.Z. and E.R.) and were considered to be present if tendons appeared diffusely enlarged or had focal nodularities. When findings were equivocal, ATs were recorded as normal. To obtain a baseline lipid profile, fasting blood was drawn after at least 4 weeks off of hypolipidemic drug treatment. Cholesterol and triglycerides were determined by standard enzymatic methods. LDL cholesterol was estimated with the Friedewald equation except in subjects with triglycerides >300 mg/dL, when it was measured by ultracentrifugation techniques as described. Polygenic hypercholesterolemia was diagnosed in subjects with LDL cholesterol >160 mg/dL, triglycerides <200 mg/dL, and absence of elevated blood cholesterol in first-degree relatives. In addition, we examined a control group of 88 normolipidemic subjects recruited from hospital personnel and lists of primary health physicians.

**Ultrasoundographic Examination**

AT sonography was performed in all of the subjects at recruitment by trained sonographers (R.G. and I.N.) using Toshiba equipment (SSA 270A, SSA 140A, Powervision, Applio) and multifrequency (7–10 MHz) electronic linear array transducers. ATs were examined with the subjects lying prone, with ankles extended beyond the examination bed and feet at 90° flexion. Special attention was paid to holding the probe perpendicular to the tendon. Measurements of thickness...

*All subjects had Achilles tendon xanthomas; 7 had associated xanthomas in other locations (4 knuckles, 2 elbows, and 1 pretibial). Values are mean±SD except for triglycerides (median and interquartile ranges).
Zaragoza subjects.

Table 1 shows the demographic and clinical characteristics and lipid profiles of the study groups. FH mutation carriers were slightly younger than the other groups, and the sex distribution differed in normolipidemic subjects, where women predominated, and FCH, where there were more men. As expected, FH and FCH subjects frequently had a family history of premature CHD. Also, subjects with FCH and polygenic hypercholesterolemia were heavier than those of other groups. Tendon xanthomas were detected by physical examination only in FH. Lipid values were consistent with the clinical diagnoses, with markedly elevated total cholesterol, LDL cholesterol, and apo B in the FH groups; high cholesterol, triglycerides, and apo B together with low HDL cholesterol in FCH, and lesser cholesterol elevation in polygenic hypercholesterolemia. Apo E genotypes were determined in FH and FCH subjects from Barcelona but were not available in the FH validation group from Zaragoza. Except for an overrepresentation of E2 in FCH, the distribution of apo E genotypes was similar in the 3 groups. There were no E2/E2 genotypes in these series.

Statistical Analyses

Numerical variables are expressed as mean±SD. Quantitative AT variables were evaluated by sex with ANCOVA analyses, using post-hoc Bonferroni testing for assessment of group differences. Pearson’s correlation coefficients were constructed to test relationships between continuous variables. We determined sex- and age-specific AT thickness threshold values for diagnosing FH based on the analysis of receiver operator characteristics (ROC) curves. ROC curves were constructed by using FH mutation carriers as the disease group and the pooled non-FH subjects as the nondisease group. A P value <0.05 was conventionally used to indicate statistical significance. SPSS software (version 11.0) was used for statistical analyses.

Validation Sets

A series of 70 FH mutation carriers from Hospital Miguel Servet, Zaragoza (Table 1), who underwent sonographic evaluation of AT thickness with the same protocol, were used to validate the performance of thresholds obtained in Barcelona. The LDLR defects in this group, determined following the same Spanish FH Register protocol, were from 36 different types and encompassed 31 missense, 14 nonsense, 13 splicing, and 12 frameshift mutations. A single subject carried the mutation R3500Q in APOB.

An additional group of 54 non-FH subjects (29 men and 25 women) from Hospital Miguel Servet with sonographic evaluation of AT thickness was used to identify the proportion of false positives obtained with the thresholds determined in the Barcelona study. They were 25 subjects with a clinical diagnosis of FCH and 29 with polygenic hypercholesterolemia, with an overall age of 48±12 years and mean levels of total, LDL, and HDL cholesterol of 295±34 mg/dL, 223±36 mg/dL, and 46±16 mg/dL, respectively, and triglycerides of 186±134 mg/dL. AT thickness measurements were performed with an ALOKA SSD-900 sonograph using a 7.5-MHz linear-array probe. Tendon echostructure was not evaluated in the Zaragoza subjects.

Results

Clinical Features and Lipid Profiles

Table 1 shows the demographic and clinical characteristics and lipid profiles of the study groups. FH mutation carriers were slightly younger than the other groups, and the sex distribution differed in normolipidemic subjects, where women predominated, and FCH, where there were more men.
lated with LDL cholesterol ($r = 0.368$ and $0.583$, respectively; $P < 0.02$) but not with HDL cholesterol. In either FH group or in FCH subjects, apo E genotypes were unrelated to AT variables.

AT thickness of the 29 FH subjects with a history of CHD (6.9 ± 3.2 mm) was significantly ($P = 0.030$) higher than corresponding values of the 97 asymptomatic individuals (5.7 ± 2.4 mm). These differences persisted ($P = 0.034$) after adjustment for sex, age, weight, and LDL cholesterol (7.0 ± 2.6 versus 5.7 ± 2.5 mm, respectively).

**Tendon Thickness Thresholds for the Diagnosis of FH**

As quantitative AT measures variably overlapped between FH and non-FH subjects (Table 2), ROC curves were used to determine sex- and age-specific threshold values for the diagnosis of FH. Because the ROC curves representing AT thickness and breadth were essentially superimposed, only the cutoff points of thickness are shown for both men and women above and below the median age of FH mutation carriers (Table 3). As seen by the areas under the curves, the ROC curves performed better in older individuals. Because the pretest probability in FH is generally low (1 in 500), cutoffs with high specificity were sought to avoid false-positive results, aggressive treatment of unaffected individuals, and undue concern for family members. These thresholds correspond to percentiles 81 to 92 of the distribution of AT thickness in pooled non-FH subjects. Because of the high specificity of these cutoffs, the values of younger FH subjects, both genetically confirmed and with no identified mutation, scatter widely above and below the threshold lines, whereas those of older subjects predominate above the lines, pointing to higher threshold sensitivity in the latter. In men, but not in women, the proportion of subjects with markedly enlarged tendons falls abruptly after age 60. A likely explanation is poor survival of FH men with more severe clinical phenotypes.

**Concordance between Clinical Examination and Sonography**

Table 4 shows the concordance between clinical examination and sonography in the diagnosis of AT xanthomas. Whereas a small proportion of tendons felt to be enlarged by the clinicians were sonographically normal, an abnormal sonogram by any of the 2 criteria of thickness above cutoff values or abnormal echostructure was found in 68% of FH mutation carriers and 46% of FH subjects without DNA diagnosis, thus increasing the diagnostic rates of physical examination by ≈ 25% in both groups. Sonographic xanthomas in normal-sized ATs were found in 10 of the 127 FH subjects.

**Validation Sets for Thickness Thresholds**

Application of cutoff values to a series of 70 FH mutation carriers from Zaragoza (Table 1) who were assessed for AT thickness with the same sonographic criteria correctly classified FH in 56 (80%) of them. When using these thresholds in another set of 58 dyslipidemic, non-FH subjects studied in the same way in Zaragoza, 53 (88%) were correctly classified as non-FH.

**Discussion**

The results of this study show that sonographic AT features improve on the clinical diagnosis of xanthomas, are normal in

Men had ATs that were thicker and larger than those of women in all of the groups. These gender differences have been observed in other studies and may be explained by the usually higher musculoskeletal development in men. Supporting prior results in control subjects, AT size was related to body weight, a plausible finding given the body support function that AT plays in skeletal physiology. In FH, but not in controls or non-FH subjects, AT size correlated positively with LDL cholesterol and negatively with HDL cholesterol. This indicates that the severity of the lipid phenotype influences extravascular cholesterol deposition only in FH. The presence of hypercholesterolemia during childhood, when tendons are growing, is a unique feature of FH that may explain these findings.

The AT thickness thresholds for diagnosing FH that we derived from ROC curves are similar to those found by Descamps et al in a like series of FH with DNA diagnosis from Belgium. These authors proposed a single cutoff point of 5.8 mm with 75% sensitivity and 85% specificity. To avoid false-positive results in a genetic disorder like FH with a low a priori probability in the population, we sought sex- and age-specific discriminatory thresholds that are less sensitive in young subjects but more specific at all ages (Table 3). When available, DNA diagnosis is clearly more sensitive, as shown in the present series, where 1 of every 3 FH mutation carriers had sonographically normal AT by any criteria (Table 4). The cutoff values performed well in validation sets of FH and non-FH individuals with genetic testing, clinical diagnoses, and AT sonograms obtained with a similar protocol, thus supporting their wider applicability, at least in a population like the Spanish one, where FH is genetically heterogeneous.

Compared with molecularly defined FH subjects, those with clinical FH and no DNA diagnosis had a milder lipid phenotype but similar clinical severity. Application of AT thickness thresholds to these individuals classified 41% of them as FH, emphasizing the uncertainty of the group’s categorization. Future refinements of molecular testing should clarify diagnoses in this ill-defined group of clinically severe hypercholesterolemias.

As reviewed recently, other imaging techniques may be used to accurately measure AT size, although none can depict xanthomas. Because sonography is a safe, low-cost, rapid, and reliable procedure, its use for the assessment of both AT size and echostructure represents a valid and practical alternative for uncovering both enlarged tendons and xanthomas that noticeably increase the yield of physical examination. The fact that the sonographic AT characteristics are normal in non-FH dyslipidemias is an added value when using this technique in the differential diagnosis of FH.
