Site-Specific Effects of PECAM-1 on Atherosclerosis in LDL Receptor–Deficient Mice

Objective—Atherosclerosis is a vascular disease that involves lesion formation at sites of disturbed flow under the influence of genetic and environmental factors. Endothelial expression of adhesion molecules that enable infiltration of immune cells is important for lesion development. Platelet/endothelial cell adhesion molecule-1 (PECAM-1; CD31) is an adhesion and signaling receptor expressed by many cells involved in atherosclerotic lesion development. PECAM-1 transduces signals required for proinflammatory adhesion molecule expression at atherosusceptible sites; thus, it is predicted to be proatherosclerotic. PECAM-1 also inhibits inflammatory responses, on which basis it is predicted to be atheroprotective.

Methods and Results—We evaluated herein the effect of PECAM-1 deficiency on development of atherosclerosis in LDL receptor–deficient mice. We found that PECAM-1 has both proatherosclerotic and atheroprotective effects, but that the former dominate in the inner curvature of the aortic arch whereas the latter dominate in the aortic sinus, branching arteries, and descending aorta. Endothelial cell expression of PECAM-1 was sufficient for its atheroprotective effects in the aortic sinus but not in the descending aorta, where the atheroprotective effects of PECAM-1 also required its expression on bone marrow–derived cells.

Conclusion—We conclude that PECAM-1 influences initiation and progression of atherosclerosis both positively and negatively, and that it does so in a site-specific manner. (Arterioscler Thromb Vasc Biol. 2008;28:1996-2002)

Key Words: PECAM-1 ▪ CD31 ▪ atherosclerosis ▪ LDL-receptor ▪ inflammation

Atherosclerosis is a chronic inflammatory disease that involves formation, at discrete regions within the vasculature, of lesions characterized by the presence of inflammatory cells, lipid deposits, and extracellular matrix deposition. Atherosclerotic lesions form preferentially at sites of vessel branching or high vessel curvature, which are exposed to low shear stresses or oscillatory or turbulent flow; however, genetic and environmental factors that determine circulating lipid levels, gender and immune status strongly influence lesion development in atherosusceptible regions. Endothelial cells respond to low shear stress in atherosusceptible regions with increased expression of adhesion molecules that enable recruitment and infiltration of immune cells that contribute to lesion development. Nevertheless, the roles of individual adhesion molecules in regulating atherosclerotic lesion development are not completely understood.

See accompanying article on page 1887

PECAM-1 is expressed on the surfaces of many cells involved in atherosclerotic lesion development, including monocytes, lymphocytes, platelets, and endothelial cells. PECAM-1 expression is equally distributed over the entire surface of the aorta, including advanced lesions, and does not appear to be affected by hemodynamic forces or lipid levels. PECAM-1 engages in homophilic and heterophilic interactions at sites of cell–cell contact. On the basis of its role as a critical component of a mechanotransducing complex that is required for expression of proinflammatory adhesion molecules at atherosusceptible sites, PECAM-1 has been predicted to have proatherosclerotic properties. However, PECAM-1 also functions to inhibit both systemic and organ-specific inflammatory responses and oxidative environment in the vasculature, on the basis of which PECAM-1 might be predicted to be atheroprotective.

The purpose of this study was to determine whether the proatherosclerotic or atheroprotective effects of PECAM-1 dominate in an in vivo situation. We therefore evaluated the effect of PECAM-1 deficiency on development of atherosclerosis in LDL receptor–deficient mice. We found that PECAM-1 has both proatherosclerotic and atheroprotective effects, with the latter dominant in the aortic sinus and the former dominant in the inner curvature of the aortic arch.
effects in LDLR-deficient mice, but that the former dominate in the inner curvature of the aortic arch whereas the latter dominate in the aortic sinus, branching arteries, and descending aorta. On the basis of these findings, we conclude that PECAM-1 influences initiation and progression of atherosclerosis both positively and negatively, and that it does so in a site-specific manner.

Methods

Animals and Diet
Mice were maintained in a facility free of well defined pathogens under the supervision of the Biological Resource Center at the Medical College of Wisconsin (MCW). Animal protocols were approved by the MCW Institutional Animal Care and Use Committee. Mice were housed in groups of 4 per cage, maintained under alternating 12-hour light and dark cycles, and had free access to food and water. LDLR-deficient (Ldlr-/-) mice,21 backcrossed for more than 10 generations onto a C57BL/6J background, were fed a normal diet (Harlan Teklad) containing 42% of calories from fat. Age- and gender-matched male and female Ldlr-/- mice were bred to obtain Ldlr-/- Ldlr-/- mice. The resulting genetic background was 98.6% C57BL/6 and 1.4% 129Sv. Six- to 8-week-old male and female Ldlr-/- mice were obtained from Jackson Laboratory, Bar Harbor, Maine. Subsequently, Ldlr-/- mice offspring were bred to obtain Ldlr-/- Ldlr-/- mice. The resulting genetic background was 98.6% C57BL/6 and 1.4% 129Sv. Six- to 8-week-old male and female Ldlr-/- Ldlr-/- mice were placed on a high-fat diet (HFD; Western-Type Diet TD 88137; Harlan Teklad) containing 42% of calories from fat. Age- and gender-matched Ldlr-/- Ldlr-/- mice gained similar amounts of weight over 24 weeks on the HFD (Table 1).

Plasma Lipid Analyses
Plasma aliquots (100 µL) of blood collected by cardiac puncture from anaesthetized mice were stored at −80°C. Levels of total cholesterol, HDL cholesterol, and triglycerides, which were determined in individual aliquots by the clinical laboratory at Children’s Hospital of Wisconsin using the Vitros 5.1 fractional shortening (FS) Chemistry System (Ortho-Clinical Diagnostics), did not differ significantly between age- and gender-matched Ldlr-/- Ldlr-/- relative to Ldlr-/- Ldlr-/- mice gained similar amounts of weight over 24 weeks on the HFD (Table 1).

Preparation of Mouse Aortas and Quantification of Atherosclerosis
The heart and aorta of each animal were perfused, dissected out, and subjected to quantification of atherosclerosis as previously described.22 Briefly, to quantitate atherosclerosis in the aortic sinus, branching arteries, and descending aorta, or total aorta as indicated.

Table. Plasma Lipid Analysis and Weight Gain of Mice After 24 Weeks on the HFD

Results are expressed as mean±SE. No statistically significant differences were found between the groups.

Lesion area was assessed using AdobePhotoshop software and expressed as a percent of the total surface area encompassed by the aortic arch, inner curvature of the arch, thoracic aorta, abdominal aorta, or total aorta as indicated.

Immunohistochemistry
Serial cryostat sections of aortic sinus adjacent to oil red O–stained sections were stained with SiriusV Red to detect collagen or antismouse CD68 (1:100, AbD Serotec) and a tyramide amplification plus kit (Perkin Elmer) to identify macrophages. Sections stained with anti-CD68 were counterstained with DAPI to visualize nuclei. Quantification of macrophage and collagen content was determined by computer-assisted image analysis and expressed as percentage of lesion area.

Ex Vivo Micro-CT Imaging and Quantification of Plaque Volume
Mouse aortic specimens were dissected free of fat and incubated overnight with 2% osmium tetroxide (OT).24,25 Prepared aortic samples were placed in a 1.5-mL plastic microcentrifuge tube and subjected to computed tomography (CT) scanning using a custom Keck microfocal X-ray imaging system at the Zablocki VA Medical Center (Milwaukee, Wisc). Details of the microfocal x-ray CT system and CT reconstruction methods were described previously.26 Briefly, the imaging system comprises a 3-μm focal-spot cone-beam X-ray source, precise specimen manipulation stage, and image intensifier coupled to a charge-coupled device (CCD) camera. Planar images (360, in 1° increments) of the aortic samples were acquired with source-to-specimen distance of 4.6 cm, source-to-detector distance of 71.5 cm, source current of 222 μA, and source voltage of 36 kV. A Feldkamp algorithm was used to produce isotropic (4973 pixels) 3-D reconstructions with 12.8 μm/pixel resolution. Floating-point grayscale voxel values were scaled to 8-bit [0 (air)-255 (punctate accumulations of OT)] for normalization and reduction of memory and processing requirements. Data were visualized and morphometrics (based on regional lesion volume) performed using multidimensional imaging software Analyze 8.0.26,27 A single observer defined threshold-based images of the vessel wall (threshold 52) and plaque (threshold 93). Lesion volumes were quantified in defined areas of the aortic arch (24.1±2.5 mm²) and proximal parts of the three major branching arteries, including the innominate (13.1±0.5 mm²), left common carotid (4.8±0.2 mm²), and left subclavian (3.6±0.2 mm²) arteries.

Creation of Radiation Chimeras
Bone marrow cells were collected from the femur and tibia of Ldlr-/- Ldlr-/- or Ldlr-/- Ldlr-/- donor mice and the small mononuclear cell-enriched fraction was injected into irradiated, 4- to 6-week-old Ldlr-/- Ldlr-/- or Ldlr-/- Ldlr-/- recipient mice as previously described.13 Transplant recipients were fed a normal Chow diet for 4 weeks, after which they were maintained on the HFD for an additional 24 weeks. Flow cytometry was performed on whole blood obtained from recipients at 12 weeks after transplantation to ensure that full engraftment had taken place, with both CD3-positive leukocytes and platelets examined for PECAM-1 expression (supplemental Figure I).
Figure 1, PECAM-1 suppresses atherosclerotic lesion development in the aortic sinuses of LDLR-deficient mice. A, Each symbol represents the mean percent atherosclerotic lesion area calculated from 4 to 6 oil red O-stained sections spanning the aortic sinus of an individual pecam-1+/−ldlr−/− (filled squares) or pecam-1−/−ldlr−/− (open circles) mouse maintained on a HFD for the indicated time. Horizontal lines indicate mean percent lesion area for each group of animals. Asterisks denote statistically significant differences between groups (**P<0.01, ***P<0.001). C, Quantitative analysis of macrophage content in aortic sinus lesions of pecam-1+/−ldlr−/− (filled bars) or pecam-1−/−ldlr−/− (open bars) mice fed a HFD for 24 weeks. Results are expressed as the mean percent of atherosclerotic lesion area occupied by CD68+ macrophages ±SE. Asterisks denote statistically significant differences between groups (**P<0.01). D, Representative anti-CD68–stained aortic sinus sections from pecam-1+/−ldlr−/− (top) and pecam-1−/−ldlr−/− (bottom) mice. E, Quantitative analysis of collagen deposition in aortic sinus lesions of pecam-1+/−ldlr−/− (filled bars) or pecam-1−/−ldlr−/− (open bars) mice fed a HFD for 24 weeks. F, Representative Sirius Red–stained aortic sinus sections from pecam-1+/−ldlr−/− (top) and pecam-1−/−ldlr−/− (bottom) mice.

Statistical Analysis
Data are presented for each individual animal or as mean±SEM. Differences between means were analyzed using 2-tailed unpaired Student t test or 2-way ANOVA followed by Bonferroni posthoc testing using GraphPad Prism 4 software (GraphPad Software Inc).

Results
PECAM-1 Deficiency Renders LDLR-Deficient Mice More Susceptible to Development of Atherosclerotic Lesions in the Aortic Sinus
To determine whether the mechanosensory or antiinflammatory role of PECAM-1 dominates in atherosclerosis, we tested the effect of PECAM-1 deficiency on development and progression of atherosclerosis in LDL receptor–deficient mice.28 We first evaluated the time course over which atherosclerotic lesions develop in the aortic sinus (Figure 1A and 1B). Both pecam-1+/−ldlr−/− and pecam-1−/−ldlr−/− mice developed similarly small atherosclerotic lesions in the aortic sinus after 8 weeks on the HFD (fractional lesion areas [FLA] −4.6±0.7% [n=7] and 3.7±0.5% [n=8], respectively). However, after 16 weeks on the HFD, atherosclerotic lesions in the aortic sinuses of pecam-1−/−ldlr−/− mice were significantly larger than were those in pecam-1+/−ldlr−/− mice (FLA −36.4±2.0% [n=8] and 25.9±1.7% [n=8], respectively) and this difference persisted through 24 weeks on the HFD (FLA −41.8±1.2% [n=14] and 36.3±1.6% [n=20], respectively). Differences in aortic sinus lesion areas between pecam-1−/−ldlr−/− and pecam-1+/−ldlr−/− mice were statistically significant when both genders were evaluated together and when each gender was evaluated separately (data not shown). Because the composition of atherosclerotic lesions, along with lesion size, is critically important in atherogenesis, cell and matrix components of the lesions were also characterized by analyzing macrophage and collagen content, respectively. After 24 weeks on the HFD, macrophage content in atherosclerotic lesions of the aortic sinus was significantly greater in pecam-1−/−ldlr−/− mice than in pecam-1+/−ldlr−/− mice (Figure 1C and 1D), whereas collagen deposition was similar between the 2 groups of mice (Figure 1E and 1F). These results indicate that PECAM-1 inhibits development of, and macrophage accumulation in, atherosclerotic lesions in the aortic sinus of LDLR-deficient mice.

PECAM-1 Deficiency Renders LDLR-Deficient Mice More Susceptible to Development of Atherosclerotic Lesions in the Descending Aorta
We next assessed the effect of PECAM-1 deficiency on development of atherosclerotic lesions in the aorta of LDLR-deficient mice by en face staining with oil red O. We found that lesion area in the aortic arch as a whole did not differ significantly between pecam-1+/−ldlr−/− and pecam-1−/−ldlr−/− mice after 24 weeks on the HFD (Figure 2). However, lesion areas in both the thoracic and abdominal aorta, and thus the

Figure 1 (Continued). (open bars) mice fed a HFD for 24 weeks. Results are expressed as the mean percent of atherosclerotic lesion area containing collagen, as identified by staining with Sirius Red, ±SE. F, Representative Sirius Red–stained aortic sinus sections from pecam-1+/−ldlr−/− (top) and pecam-1−/−ldlr−/− (bottom) mice.
PECAM-1 Affects Atherosclerotic Lesion Development in the Aortic Arch in a Site-Specific Manner

We observed a distinct pattern of plaque development in aortic arches of pecam-1<sup>−/−</sup>ldlr<sup>−/−</sup> relative to pecam-1<sup>−/−</sup>ldlr<sup>+</sup> mice by en face staining with oil red O. The pecam-1<sup>−/−</sup>ldlr<sup>−/−</sup> mice had significantly larger lesions along the inner curvature of the arch but smaller lesions in branching arteries compared to the pecam-1<sup>−/−</sup>ldlr<sup>+</sup> mice (Figure 3A and 3B). We therefore decided to evaluate the effect of PECAM-1 deficiency on development of atherosclerotic lesions in the aortic arch in more detail using another method. We used microcomputed tomography (micro-CT), which is a powerful imaging technique for visualization of small specimens. Micro-CT has been recently used to visualize the artery wall and early atherosclerotic lesions both with and without OT as a contrast agent. Micro-CT images revealed striking differences in plaque localization in pecam-1<sup>−/−</sup>ldlr<sup>−/−</sup> relative to pecam-1<sup>−/−</sup>ldlr<sup>+</sup> mice. Specifically, in pecam-1<sup>−/−</sup>ldlr<sup>−/−</sup> mice, lesions were less extensive in the aortic branches and more extensive along the inner curvature of the aortic arch (Figure 3C). In contrast, pecam-1<sup>−/−</sup>ldlr<sup>−/−</sup> mice developed substantial atherosclerosis in branching arteries but few lesions along the inner curvature of the arch (Figure 3). By visualizing the specimen in 3 dimensions, it is apparent that plaque was extensively distributed along the inner curvature of the arch and only minimally present along the lateral wall of the innominate artery (IA) and left common carotid artery (LCCA) of pecam-1<sup>−/−</sup>ldlr<sup>−/−</sup> mice (supplementary Figure II), whereas plaque was broadly distributed along the lateral walls of all 3 branching arteries and restricted to small patches along the inner curvature of the arch in pecam-1<sup>−/−</sup>ldlr<sup>−/−</sup> mice (supplementary Figure III). We also used OT in micro-CT to quantify plaque volume over defined areas of vessel wall within discrete regions of the aortic arch. We found that pecam-1<sup>−/−</sup>ldlr<sup>−/−</sup> mice had sig-
significantly more plaque volume than did pecam-1+/lacZ mice along the inner curvature of the arch; however, this was offset by the presence of significantly greater plaque volume in the branching arteries of pecam-1−/−/ldlr−/− relative to pecam-1+/+/ldlr−/− mice, such that plaque burden in the total aortic arch as a whole was similar in pecam-1+/+/ldlr−/− and pecam-1−/−/ldlr−/− mice (Figure 3D). Overall, these results indicate that PECAM-1 expression in LDLR-deficient mice is proatherosclerotic along the inner curvature of the aortic arch but atheroprotective in aortic branches.

**Endothelial Cell PECAM-1 Expression Protects Against Development of Atherosclerosis in the Aortic Sinuses of LDLR-Deficient Mice**

PECAM-1 is expressed on both endothelial cells and bone marrow–derived leukocytes and platelets, and is capable of transducing signals that affect the function of cells from both of these compartments. It was therefore important to determine whether the effects of PECAM-1 on atherosclerosis required its expression on endothelial cells, bone marrow–derived cells, or both. We created bone marrow chimera ldlr−/− mice that selectively expressed PECAM-1 either on endothelium or bone marrow–derived cells (supplemental Figure I), and measured atherosclerotic lesion sizes after feeding these mice a HFD for 24 weeks. Unfortunately, the bone marrow transplantation experiments did not recapitulate decreased lesion formation in the lesser curvature of the arch in pecam-1−/− mice. The lesion area along the inner curvature of the arch of ldlr−/− mice was comparable in pecam-1+/+ recipients of pecam-1+/−/ldlr−/− marrow and pecam-1−/− recipients of pecam-1−/−/ldlr−/− marrow (supplemental Figure IV); therefore, we could not use bone marrow chimera mice to determine whether endothelial or bone marrow–derived leukocyte or platelet expression of PECAM-1 enhances lesion development in this region. However, like untransplanted pecam-1−/−/ldlr−/− relative to pecam-1+/−/ldlr−/− mice, pecam-1−/− recipients of pecam-1−/− bone marrow developed larger lesions in the aortic sinus (Figure 4A) and total aorta (Figure 4B) relative to pecam-1+/+ recipients of pecam-1+/− marrow. Thus, bone marrow chimera mice could be used to determine the effects of endothelial versus hematopoietic cell expression of PECAM-1 on lesion development in the aortic sinus and total aorta of ldlr−/− mice.

In the aortic sinus, lesions that developed in pecam-1+/+ recipients of pecam-1−/− marrow were similar in size to those of pecam-1+/+ recipients of pecam-1+/− marrow, and significantly smaller than the lesions that developed in pecam-1−/− recipients of pecam-1−/− marrow (Figure 4A). Also, lesions that developed in the aortic sinuses of pecam-1−/− recipients of pecam-1+/− marrow were similar in size to those of pecam-1−/− recipients of pecam-1−/− marrow and significantly larger than the lesions that developed in pecam-1−/− recipients of pecam-1+/− marrow (Figure 4A). These results indicate that endothelial cell expression of PECAM-1 inhibits development of atherosclerotic lesions in the aortic sinuses of ldlr−/− mice. Interestingly, mice that were missing PECAM-1 from either endothelial cells, bone marrow–derived leukocytes or platelets, or both exhibited a trend toward increased lesion

**Figure 4.** The effect of endothelial cell vs blood cell PECAM-1 expression on development of atherosclerosis in LDLR-deficient mice. A, Endothelial cell PECAM-1 protects against development of atherosclerosis in the aortic sinus. Each symbol represents the mean percent atherosclerotic lesion area calculated from 4 to 6 oil red O-stained sections spanning the aortic sinus of an individual pecam-1+/+ldlr−/− (filled symbols) or pecam-1−/−ldlr−/− (open symbols) recipient mouse transplanted with pecam-1+/+ldlr−/− (squares) or pecam-1−/−ldlr−/− (circles) donor bone marrow and maintained on a HFD for 24 weeks. Horizontal lines indicate the mean percent aortic sinus lesion area for each group of animals. Asterisks denote statistically significant differences between groups (*P<0.05, **P<0.01). B, Endothelial cell and blood cell PECAM-1 expression are required for PECAM-1-mediated protection against development of atherosclerosis in the aorta. Each symbol represents the percent of total area of the indicated section of aorta that stained positively for oil red O in an individual pecam-1+/+ldlr−/− (filled symbols) or pecam-1−/−ldlr−/− (open symbols) recipient mouse transplanted with either pecam-1+/+ldlr−/− (squares) or pecam-1−/−ldlr−/− (circles) donor bone marrow and maintained on a HFD for 24 weeks. Horizontal lines indicate mean percent lesion area in the indicated aortic section, including the thoracic aorta, abdominal aorta, and total aorta (thoracic arch + thoracic aorta + abdominal aorta), for each group of animals. Asterisks denote statistically significant differences between groups (*P<0.05, **P<0.01).
Discussion

The major finding of this study is that PECAM-1 expression affects development of atherosclerosis differently at different lesion-prone sites of the vasculature. Specifically, PECAM-1 is proatherosclerotic in the inner curvature of the aortic arch, but atheroprotective in the aortic sinus, branching arteries, and descending aorta. The atheroprotective effect of PECAM-1 in the aortic sinus requires PECAM-1 expression only on endothelial cells, whereas PECAM-1 expression on both endothelial cells and bone marrow–derived cells is required for its atheroprotective effects in the descending aorta.

The proatherosclerotic effect of PECAM-1 in the inner curvature of the arch is consistent with its role as part of a mechanostimulatory complex on endothelial cells that activates NF-κB in response to low shear stress and induces expression of adhesion molecules that enable recruitment of inflammatory cells into the lesion. A mechanostimulatory function for PECAM-1 is supported by the findings in many, but not all, studies that PECAM-1 facilitates responses of cultured endothelial cells to osmotic and fluid shear stresses. Previous studies have established that PECAM-1 is rapidly phosphorylated on cytoplasmic tyrosine residues in cultured endothelial cells exposed to fluid shear or osmotic stress; however, whether PECAM-1 tyrosine phosphorylation is required for its mechanostimulatory function is not yet known.

The atheroprotective effect of PECAM-1 in the aortic sinus, branching arteries, and descending aorta indicates that PECAM-1 normally inhibits development of atherosclerosis in these regions of the vasculature. Our studies of bone marrow chimeric mice revealed that the cells on which PECAM-1 must be expressed to inhibit lesion development vary by vascular region. Specifically, in both the aortic sinus and descending aorta, the atheroprotective effect of PECAM-1 required its expression on endothelial cells; in the aortic sinus, PECAM-1 expression on endothelial cells alone was sufficient for its inhibitory function. Two functions of the endothelium that impact lesion development in atherosusceptible regions include maintenance of the vascular permeability barrier and insurance of nitric oxide (NO) bioavailability. PECAM-1 has been shown to support maintenance of vascular integrity in at least 4 different models of inflammation, including intradermal injection of histamine, autoimmune encephalomyelitis, collagen-induced arthritis, and lipopolysaccharide (LPS)-induced endotoxemia. PECAM-1 deficiency has also been shown to affect NO bioavailability, either as a consequence of decreased production of NO or increased production of reactive oxygen species. Thus, either increased vascular permeability or decreased NO bioavailability could contribute to the increased atherosclerosis observed in the aortic sinuses and descending aortas of mice with PECAM-1−/− deficient relative to PECAM-1−/− positive endothelium.

The inhibitory effect of PECAM-1 on lesion development in the aorta as a whole, in contrast, required its expression not only on endothelial cells but also on hematopoietic cells. The hematopoietic cells thought to play crucial roles in atherosclerotic lesion development include monocytes, T lymphocytes, and platelets. There is ample evidence that PECAM-1 inhibits platelet responsiveness, and PECAM-1 is also capable of interfering with both macrophage-mediated phagocytosis of viable cells and T cell receptor–mediated signaling pathways. Indeed, loss of PECAM-1 from circulating T cells correlated with occurrence of atherothrombotic plaque complications in humans and mice. Furthermore, in vivo administration of PECAM-1/IgG fusion proteins reduced lesion sizes in atherosusceptible mice coincident with blunted T cell activation, increased numbers of circulating regulatory T cells, and decreased infiltration of T cells into accumulating plaque. Collectively, these studies support the conclusion that interactions between PECAM-1–expressing endothelial cells and either platelets, monocytes, or T cells may decrease atherosclerosis in aortas of PECAM-1−/− positive relative to PECAM-1−/− negative mice. Studies in which the PECAM-1 gene is knocked out in specific types of hematopoietic cells are needed to determine the extent to which PECAM-1 expression by any one of these cell types normally interferes with development of atherosclerosis.

Finally, our findings indicate that PECAM-1 has both proatherosclerotic and atheroprotective effects on the vasculature; however, each of these opposing effects dominates in a different region of the vasculature. Thus, the inner curvature of the arch is more strongly influenced by the mechanostimulatory and therefore proatherosclerotic function of PECAM-1, whereas other atherosusceptible regions of the vasculature are more strongly influenced by its antiinflammatory and therefore atheroprotective effects. A possible explanation for the differential sensitivity of these regions to the mechanosensory versus antiinflammatory roles of PECAM-1 is that PECAM-1 might influence the type or magnitude of hemodynamic shear stress to which different regions of the vasculature are exposed, which can be addressed by comparing the hemodynamic properties of PECAM-1 versus PECAM-1−/− aortas. Alternatively, PECAM-1 might contribute in different ways to the responses of cells in different regions of the vasculature, even if they are exposed to the same shear stresses. This possibility is consistent with the concept that site-specific responses to systemic factors modulate how atherosclerosis develops in different atherosusceptible regions. In either case, by demonstrating that PECAM-1 both promotes and impedes development of atherosclerotic lesions in site-specific ways, our findings provide a more complete understanding of the factors that interact in complex ways to control initiation and progression of atherosclerosis.
