Abstract—Coronary artery calcification is a well-established predictor of future cardiac events; however, it is not a predictor of unstable plaque. The intimal calcification of the atherosclerotic plaques may begin with smooth muscle cell apoptosis and release of matrix vesicles and is almost always seen microscopically in pathological intimal thickening, which appears as microcalcification (≥0.5 μm, typically <15 μm in diameter). Calcification increases with macrophage infiltration into the lipid pool in early fibroatheroma where they undergo apoptosis and release matrix vesicles. The confluence of calcified areas involves extracellular matrix and the necrotic core, which can be identified by radiography as speckled (≤2 mm) or fragmented (>2, <5 mm) calcification. The calcification in thin-cap fibroatheromas and plaque rupture is generally less than what is observed in stable plaques and is usually speckled or fragmented. Fragmented calcification spreads into the surrounding collagen-rich matrix forming calcified sheets, the hallmarks of fibrocalcific plaques. The calcified sheets may break into nodules with fibrin deposition, and when accompanied by luminal protrusion, it is associated with thrombosis. Calcification is highest in fibrocalcific plaques followed by healed plaque rupture and is the least in erosion and pathological intimal thickening. The extent of calcification is greater in men than in women especially in the premenopausal period and is also greater in whites compared with blacks. The mechanisms of intimal calcification remain poorly understood in humans. Calcification often occurs in the presence of apoptosis of smooth muscle cells and macrophages with matrix vesicles accompanied by expression of osteogenic markers within the vessel wall. (Arterioscler Thromb Vasc Biol. 2014;34:724-736.)

Key Words: coronary artery disease ■ pathology ■ vascular calcification

Three main types of vascular calcification have been reported: medial Mönckeberg arterial calcification, intimal calcification associated with atherosclerosis, and infantile calcification. In the current review article, we will focus on (intimal) calcification related to coronary atherosclerosis, although other beds will be also mentioned. Atherosclerotic calcification has intrigued pathologists, cardiologist, and researchers of lipid metabolism and inflammation for more than a century; however, despite extensive research in this area, our mechanistic understanding of atherosclerotic calcification in humans remains limited. An important factor contributing is the lack of good animal models of human atherosclerosis. This deficiency can be explained by the different life span of species that cannot be compensated in contemporary animal models. Human atherosclerosis progresses over decades before becoming manifest in a large majority of cases in the sixth and seventh decades, whereas atherosclerotic animal models typically involve breeding periods ranging from months to a few years. By far, the most studied animal being the genetically modified mouse, with either apolipoprotein E or the low-density lipoprotein receptor deficient, that develop atherosclerosis via increases in serum very-low-density lipoprotein and disruption of cellular low-density lipoprotein uptake, respectively, resulting in excessive accumulation of lipids in the vascular wall. In these animals, minimal calcification and no thrombosis is seen, which is significantly different from the observations made in humans. Nevertheless, the mouse model has been extremely useful for the understanding of basic pathways involved in atherosclerosis.1,2

Atherosclerosis occurs in the presence of risk factors, especially hyperlipidemia, and manifests focally at branch points as a chronic inflammatory process induced by lipid deposits in the arterial wall. Calcification of the atherosclerotic plaque begins in middle age and is ubiquitously observed in older individuals. The disease is highly prevalent worldwide but relatively few have a clinical event.3 Clinical manifestations of the coronary disease include myocardial infarction, unstable and stable angina, and sudden coronary death (SCD); carotid disease includes stroke and transient ischemic attack, whereas peripheral artery disease manifestation includes claudication and critical limb ischemia. In patients dying from coronary thrombosis, the main cause is acute plaque rupture, less frequently erosion, and least often calcified nodule.4
In this review, we will concentrate on the human coronary atherosclerotic calcification with emphasis on plaque progression. The various plaque types and the degree of narrowing will be described. Furthermore, we will review the difference in its prevalence among men and women and how race may also influence the extent of calcification. Although pathological mechanisms of calcification are likely multifactorial, there is little consensus and therefore we will emphasize mainly on those that may be more applicable to humans.

**Atherosclerosis Plaque Progression**

The natural history of atherosclerosis is considered to be a dynamic process varying from early lesion development to more advanced plaques complicated by acute thrombosis. Intimal thickening begins with an increase in smooth muscle cells (SMCs) and proteoglycan–collagenous matrix with little or no infiltration of inflammatory cells, which is classified as adaptive intimal thickening (AIT), and is related to blood flow. Atherosclerotic plaques have been described to begin as fatty streak with accumulation of lipid-laden foamy macrophages and SMCs, although this lesion is known to regress. To our knowledge, the earliest progressive atherosclerotic lesion is pathological intimal thickening (PIT), which is characterized by the presence of acellular lipid pools within the intima but close to the media where there is a lack of SMCs but there is an abundance of proteoglycans and lipid deposition. As plaques progress, there is infiltration by macrophages and T lymphocytes close to the lumen and remote from the lipid pools.

The more advanced stage of atherosclerotic lesion is classified as fibroatheroma, which is characterized by the presence of a lipid-rich necrotic core encapsulated by fibrous tissue. The early phase of fibroatheroma (early fibroatheroma) shows infiltration of macrophages into the lipid pool and focal loss of proteoglycans and collagen matrix. The accumulation of free cholesterol in early fibroatheromas is not extensive, whereas the late fibroatheroma consists of discrete collections of cellular debris, increased free cholesterol, and near-complete depletion of extracellular matrix.

Thin-cap fibroatheroma (TCFA), conceptually referred to as vulnerable plaque, consists of a large necrotic core harbored by a thin (<65 μm) fibrous cap which is heavily infiltrated by macrophages and to a lesser extent T lymphocytes with a paucity or absence of SMCs. This well-characterized ominous lesion is considered to be the prelude of plaque rupture. The only difference between plaque rupture and TCFA is a disrupted thin fibrous cap infiltrated by macrophages and T cells and a larger necrotic core.

In contrast to plaque ruptures, erosions frequently occur in moderately diseased arteries and the fibrous cap remains intact. In erosion lesions, the luminal surface underneath the thrombus lacks endothelium and is rich in proteoglycans and SMCs. The underlying plaque is composed of either PIT or fibroatheromas without an extensive necrotic core, hemorrhage, or calcification. The cause of plaque erosions remains unknown; however, we think it may be a consequence of vasospasm.

Healed thrombi include those occurring from healed plaque rupture and erosion. The provisional matrix at the site of healing typically consists of an organizing platelet-fibrin–rich thrombus that is infiltrated by SMCs and granulation tissue with accumulated proteoglycans and type III collagen, which eventually converts into a type I rich collagen scar. Healed ruptures may be single or consecutive events resulting in multiple layers of necrotic cores interspersed by fibrous tissue. With respect to the sequence of ruptures, the earliest intima can be found in deeper intima suggestive of previous thrombotic events, which sequentially leads to increased plaque burden and luminal narrowing.

**Progression of Calcification in the Course of Atherosclerosis**

The progression of calcification may begin with microcalcification (≥0.5 μm, typically <15 μm), which is seen following special stains for calcification, for example, von Kossa stain, Alizarin red (Figure 1A). Early calcification is apparent within the lipid pools as stippling by calcium stains which likely originates from SMC apoptosis or matrix vesicles and is generally ≥1 μm in size that can be appreciated by light microscopy. Electron microscopic examination of vascular wall has revealed that the initial calcification occurs in matrix vesicles which vary in size from 100 to 700 nm in diameter. The loss of intact SMCs has also been identified by the presence of prominent basement membrane which stains strongly with periodic acid–Schiff and contains central areas of apoptotic bodies derived from SMCs (Figures 1A and 2). Calcification is typically located in the intima close to the internal elastic lamina.

Microcalcification may also occur from macrophage releasing matrix vesicles or from apoptosis. Macrophage apoptosis may result in a different morphological appearance of calcification. Although SMC apoptosis results in fine microcalcification, macrophage apoptosis exhibits large punctate, blocky appearance (Figure 1B and 1C). Microcalcification is frequently observed in TCFA, despite the fact that its contribution to plaque vulnerability remains to be determined. These microcalcifications often coalesce into larger masses and involve both the necrotic core and the surrounding collagen-rich extracellular matrix to form speckled and fragmented calcification. This particular pattern also starts in the deeper region of the necrotic core close to the internal elastic lamina (Figure 1D and 1E). Further progression of calcification is seen as extension from the outer rim of the necrotic core (Figure 1F) into the surrounding collagenous matrix. Importantly, the central core either becomes fully calcified or may remain noncalcified at this stage. Nevertheless further progression of disease results in calcified plaque that forms calcified sheets or plates (Figure 1G and 1H). Calcified plaques may fracture which results in the formation of nodular calcification that is accompanied by fibrin deposition (Figure 1I). These nodules may protrude into the lumen or into the media. When the former occurs, it results in luminal protrusion and there is discontinuity of the overlying collagen and endothelium with acute thrombosis. The latter calcified nodules are rare occurring in 2% to 7% of cases with thrombosis but are more frequent (4%–14%) in the carotid plaques.

Bone formation can rarely be observed in areas of arterial calcification (Figure 1J), particularly in heavily calcified segments, which indicates osteogenesis induced at sites of arterial calcification. The incidence of bone formation has been
Figure 1. Progression of coronary calcification. Nondecalcified arterial segments (A and B) and decalcified segments (C–J) were serially cut for the microscopic assessment. A, Pathological intimal thickening (PIT) characterized by lipid pool (LP) that lacks smooth muscle cells.
reported to be 19% in peripheral vascular disease in patient who underwent lower limb amputation. However, to our knowledge, the frequency of bone formation in coronary arteries has not been reported, but is uncommon. Several lines of evidence have suggested that arterial calcification shares features with skeletal bone formation and calcification, such as chondrocyte and osteoblast differentiation, mineralization, bone matrix deposition, and bone resorption. Bone-related proteins including bone morphogenic protein (BMP)-2 and BMP-4, bone sialoprotein, osteocalcin, osteonectin, osteopontin, and osteoprotegerin have been reported to be present in calcified atheromas, whereas carboxylated MGP is highly expressed in fibrocalcific plaques from SCD victims showed positive staining for osteoprotegerin (OPG), osteopontin (OPN), and matrix Gla protein (MGP). Early necrotic core (NC; B) not only lacks SMCs but also is infiltrated by macrophages which eventually undergo apoptosis and calcification, which is observed as punctate (≥15 μm) areas of calcification. The microcalcification in early NC shows variable amounts of staining for macrophage CD68 antigen; however, von Kossa staining clearly shows relatively larger punctate areas of calcification resulting from macrophage cell death within the NC as compared with microcalcification of dying SMCs. These calcified macrophages show colocalization of bone-related proteins. Substantial amount of macrophage calcification can be observed in early NC (C), but the degree of calcification in NC typically increases toward the medial wall where fragmented calcifications can be seen (D). Microcalcification resulting from macrophage or SMC deaths can also be detected within a thin fibrous cap and may be associated with plaque rupture (E). Calcification generally progresses into the surrounding area of the NC (F), which leads to the development of sheets of calcification where both collagen matrix (G) and NC itself are calcified (H). Nodular calcification may occur within the plaque in the absence of luminal thrombus and is characterized by breaks in calcified plates with fragments of calcium separated by fibrin (I). Ossification may occur at the edge of an area of calcification especially in nodular calcification (J). Immunohistochemical stainings in A and B were performed with the use of antibodies for CD68 (dilution 1:800; Dako, Carpinteria, CA), α-SMA (dilution 1:400; Dako), OPG (dilution 1:50; Novus Biologicals, LLC, Littleton, CO), OPN (dilution 1:400; generously provided by Larry W. Fisher, PhD, National Institute of Health, Bethesda, MD), and MGP (dilution 1:200; Enzo Life Science, Farmingdale, NY), respectively. H/E indicates hematoxylin and eosin; and Thr, thrombus.

Figure 1 (Continued). (SMCs; negative for α-smooth muscle actin [α-SMA]) and the presence of apoptotic SMCs which can be identified by prominent basement membrane which stains positive with periodic acid–Schiff (PAS), and the arrows point to in the high-power image (top right corner). Early microcalcification (≥0.5 μm, typically <15 μm in diameter) likely results from SMC apoptosis, and calcification is detected by von Kossa staining within the LP (corresponding with a boxed area in the Movat image) where bone-related proteins such as osteoprotegerin (OPG), osteopontin (OPN), and matrix Gla protein (MGP) are detected. Early necrotic core (NC; B) not only lacks SMCs but also is infiltrated by macrophages which eventually undergo apoptosis and calcification, which is observed as punctate (≥15 μm) areas of calcification. The microcalcification in early NC shows variable amounts of staining for macrophage CD68 antigen; however, von Kossa staining clearly shows relatively larger punctate areas of calcification resulting from macrophage cell death within the NC as compared with microcalcification of dying SMCs. These calcified macrophages show colocalization of bone-related proteins. Substantial amount of macrophage calcification can be observed in early NC (C), but the degree of calcification in NC typically increases toward the medial wall where fragmented calcifications can be seen (D). Microcalcification resulting from macrophage or SMC deaths can also be detected within a thin fibrous cap and may be associated with plaque rupture (E). Calcification generally progresses into the surrounding area of the NC (F), which leads to the development of sheets of calcification where both collagen matrix (G) and NC itself are calcified (H). Nodular calcification may occur within the plaque in the absence of luminal thrombus and is characterized by breaks in calcified plates with fragments of calcium separated by fibrin (I). Figure 2. Advanced human atherosclerotic plaque showing apoptotic smooth muscle cells (SMCs). A, Stained by the terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) technique. B, The same TUNEL-labeled section subsequently stained by periodic acid–Schiff (PAS) stain (TUNEL+PAS technique). A labeled nucleus is present in a cell-poor area in the fibrous cap (A), and this TUNEL-positive nucleus belongs to a cell that is surrounded by a prominent cage of PAS-positive basal laminae (B). This points to an SMC undergoing apoptotic cell death. Most of the SMCs in this region do not express α-SMC actin. Adjacent to this cell are PAS-positive empty cages of thickened basal laminae. C, Transmission electron microscopy image of an advanced human atherosclerotic plaque. Two SMCs are demonstrated that are completely disintegrated into myeloid vesicles (granulovesicular degeneration). The prominent basal laminae (bl) around these clusters of vesicles led us to conclude that the vesicles are of SMC and not of macrophage origin. Reproduced with permission from Kockx et al. areas in coronary plaques from SCD victims. Moreover, clinical imaging studies in patients with acute coronary syndromes as well as autopsy observations in SCD victims have demonstrated less calcification in ruptured or vulnerable plaques as compared with stable plaques (Figure 4). These findings support the notion that calcium generally confers stability to plaques rather than the opposite. Nevertheless, as it stands, location of the calcification seems to be paramount. Vengrenyuk et al have reported that microcalcification within a thin fibrous cap (typically 10 μm in diameter) facilitates plaque rupture through local increase in stress that leads to interfacial debonding (Figure 1E). However, their more recent article shows that microcalcification >5 μm in diameter may be harmful and can predict plaque rupture, whereas microcalcification <5 μm in diameter is seemingly less harmful.

We have previously reported that maximum calcification is seen in healed plaque ruptures, followed by fibroatheroma, TCFA, plaque rupture, with least calcification seen in plaque erosion and PIT. The degree of calcification by plaque type in SCD victims is shown in Figure 4. The mean calcified area is maximum in fibrocalcific lesion and least in AIT/fibrous plaques or erosion. Total occlusions display variable degrees of calcification, and the dimension of calcification depends on the underlying plaque morphology as well as the length of the thrombus.

Mauriello et al have recently shown that calcification is maximum in individuals dying from acute myocardial infarction relative to control patients dying from noncardiac causes but with ≥1 coronary artery showing >50% stenosis. However, the coronary calcification did not correlate with presence of unstable characteristics, thus suggesting that coronary calcification is a predictor of generic risk of acute events but is not useful for identifying vulnerable lesions. We have shown that age at presentation may be an important predictor of calcification among unstable and stable plaques. There seems to be an inverse relationship between calcification, plaque stability, and age. Although patients presenting in the fourth decade with ruptured/TCFA lesions (unstable plaques) showed greater calcification than those exhibiting stable plaques, no differences were observed in the fifties and sixties. In contrast, significantly greater calcification was observed in the seventies in stable than in unstable plaques.

Results from Computed Tomography

Although the use of computed tomography (CT) for the detection of future cardiovascular events has engendered a fair amount of controversy in the past, the level of evidence has tremendously increased and has been given a level IIa recommendation for risk stratifying individuals at intermediate risk (10%–20%, 10-year risk). Although the risk of future coronary event is higher in asymptomatic individual with a high absolute calcium score, it is the risk for an individual patient that is best predicted by comparing calcium score percentiles; patients with a calcium score >75th percentile had 19 times the risk of having a hard coronary event as compared with those with a score of <25th percentile, whereas the risk of events in patients in the upper risk factor quartile was 6.5 times greater than that of patients in the lowest quartile. Recent studies have demonstrated that individuals with...
low-density lipoprotein cholesterol and no reported risk factors but with any coronary artery calcium present have a greater likelihood of coronary heart disease as compared with those without any calcification during a median follow-up of 5.4 years. Similarly, absence of coronary calcification imparts a low risk of future coronary events.

According to the literature, CT can only identify calcification areas of 1.03 to 1.37 mm² in size; that is, 3 to 4 contiguous pixels within a plaque area of 5 mm². Therefore, microcalcification seen in early plaques (PIT and early fibroatheroma) will not be identified by CT; this includes calcification of both SMCs as well as macrophages. Only once aggregation of calcium occurs in fibroatheromas, which is almost always observed near the intimal medial border involving both large areas of adjoining necrotic core and collagen, can CT identify these lesions.

Determinants of Calcification: Sex and Race Differences

Sex differences in calcification have been appreciated for a long time (Figure 5). The incidence of coronary artery disease in women is delayed by 10 to 15 years as compared with men, likely attributable to the protective effects of estrogen. The effect of estrogen therapy on coronary calcification was studied in women aged 50 to 59 years during a 7-year period of treatment. Calcification burden was significantly less in women assigned to estrogen substitution as compared with those receiving placebo. However, it must be stated that a prior large study, the Women’s Health Initiative (WHI) trial of conjugated equine estrogen given in postmenopausal women who had undergone hysterectomy, reported a hazard ratio of 0.95 (confidence interval, 0.79–1.16) for nonfatal myocardial infarction plus fatal coronary heart disease in those receiving estrogen versus placebo. Nevertheless, secondary analysis by age group suggested that the results were different in younger versus older women. In our registry of 108 human hearts (70 men; mean age, 50.4±12.2 years and 38 women; mean age, 49.6±12.2 years) who died of SCD, the extent of coronary calcification was assessed on a semiquantitative scale (grade 0=no calcification; grade 1=calcification <40 μm in diameter; grade 2=>40 μm in diameter involving only 1 quadrant; grade 3=in 2 arterial
blacks,45 and bone density is inversely related to aortic calcification.46 There may be inherent genetic predisposition for coronary calcification in blacks and whites, which remains to be determined. Huang et al47 showed that race-related genes, such as GAB2, which is expressed at a lower level in blacks and also in those with low calcification, may be another explanation for the lower prevalence of calcification in blacks. Furthermore, it has been reported that soluble epoxide hydrolase gene polymorphism is associated with coronary calcification in blacks, but not in whites.48 Although multiple variations of gene expression are likely to be involved,47 the precise genetic impact on calcification remains to be elucidated.

Calcification, Vascular Remodeling, and Luminal Stenosis

Sangiorgi et al49 demonstrated that arterial calcification correlated with plaque burden, but had only a weak correlation with lumen narrowing (Figure 6A and 6B). Because coronary calcification has been shown to be a predictor of future events, it is not surprising that there is a good correlation between calcification and plaque area. The poor correlation between calcification and lumen area needs to be interpreted with caution because effective lumen area represents multifactorial processes. Conventionally, lumen area decreases as plaque burden increases beyond 40% stenosis, introducing a negative correlation among these parameters. A deviation from this notion is expected when there is compensatory enlargement of the vessel, termed positive remodeling. This relationship was clearly demonstrated by Glagov et al50 who showed that lumen area does not decrease until the lesion occupies ≥40% of the internal elastic lamina area. Compensatory enlargement may be the main explanation why there is no correlation between calcification and lumen area in early plaque development when calcification is progressing. The poor correlation between calcification area and lumen area can also be partially explained on the basis of plaque morphology with highly fibrotic plaques being associated with negative remodeling.51 Luminal narrowing may only occur in advanced atherosclerotic lesions after the vascular capacity of compensatory enlargement has exhausted. We investigated the association between arterial remodeling and plaque components and have shown that arterial expansion was strongly correlated with calcification, macrophage infiltration, and lipid core.51

Another intriguing finding is that there is an excellent correlation between percent stenosis and the prevalence of

![Figure 5. Bar graphs showing total calcification score in sudden coronary death victims stratified by decade in male and female (A) as well as in black and white (B). quadrants; grade 4=in 3 arterial quadrants; grade 5=involving the entire arterial circumference).48 When stratified by decades, the extent of calcification was greater in men as compared with women up to the sixties, whereas in the seventies, the prevalence was similar, suggesting that coronary calcification develops rapidly during the postmenopausal period (Figure 5A). Our laboratory previously reported that the degree of calcification in postmenopausal women is 3 times higher than in premenopausal women assessed in men and women dying suddenly.42 It has also been reported that race affects the degree of calcification. In the MESA in asymptomatic individuals aged 45 to 84 years after adjusting for various clinical parameters, the relative risk for calcification was 0.78 (95% confidence interval, 0.74–0.82) in blacks, 0.85 (95% confidence interval, 0.79–0.91) in Hispanics, and 0.92 (95% confidence interval, 0.85–0.99) in Chinese relative to the white race.43 Our autopsy assessment in SCD victims showed that the total coronary calcification scores when stratified by decades was consistently greater in whites as compared with blacks in all decades (Figure 5B).38 This finding is in line with previous clinical observations showing that the prevalence and extent of calcification was substantially greater in whites as compared with blacks when assessed by CT.44 Although the mechanisms responsible for the racial difference in coronary calcification are not fully understood, several possible explanations have been proposed. Bone mineral density is less in whites than in blacks,52 and bone density is inversely related to aortic calcification.46 There may be inherent genetic predisposition for coronary calcification in blacks and whites, which remains to be determined. Hu...
calcification (%) as well as mean calcification area (square millimeter; Figure 6C). The positive correlation between percent stenosis and the degree of calcification may be partly explained by the relationship between plaque morphology and percent stenosis. When percent stenosis is stratified by decades, the prevalence of complex lesions and calcification increase incrementally. In other words, complex lesions, especially healed plaque ruptures, are frequently observed in higher-grade stenosis and are likely to be accompanied by greater calcification (Figure 7).

**The Location of Coronary Calcification**

Our data indicate that calcified area is greater at proximal than in distal locations in the 3 main epicardial arteries (left anterior descending artery, left circumflex artery, right coronary artery) in patients presenting with coronary artery disease at a mean age of 64±14 years. This has also been reported by Sangiorgi et al in 13 patients with only 2 having died of coronary artery disease. A recent longitudinal intravascular ultrasound study showed that plaque burden was greatest in proximal and least in distal coronary arteries. However, calcification was similar in proximal and middle and least in the distal arteries in individuals presenting with acute coronary syndromes with a median age of 58 years. This observation is in keeping with the previous notion that plaque burden correlates with calcification as reported by histology, angiography, intravascular ultrasound, and now by cardiac CT.

**Mechanisms of Atherosclerotic Calcification**

As stated above, atherosclerotic intimal calcification is different from medial Mönckeberg calcification, and the latter occurs independently from intimal calcification (Figure 8). Most importantly, medial calcification is not associated with lipid deposition or inflammation. Medial calcification is first appreciated within the elastic lamellae, both within the media and in the internal elastic lamina, followed by medial SMC. It is accelerated in the presence of diabetes mellitus and chronic renal failure. The SMCs lose their contractile phenotype...
(α-actin and SM22-α) and gain osteochondrogenic markers such as osteopontin, Runt-related transcription factor 2, also known as core-binding factor subunit α-1 (Runt-related transcription factor 2/core-binding factor subunit α-1), alkaline phosphatase, and osteocalcin. It has also been shown that MGP-null mice undergo spontaneous arterial medial...

Figure 8. Schematic illustrating 4 nonmutually exclusive theories for vascular calcification: (1) cell death leading to release of apoptotic bodies and necrotic debris that may serve to nucleate apatite at sites of injury; (2) circulating nucleational complexes released from actively remodeling bone or matrix vesicular released locally; (3) loss of inhibition as a result of deficiency of constitutively expressed tissue-derived and circulating mineralization inhibitors leads to default apatite deposition; and (4) induction of bone formation resulting from altered differentiation of vascular smooth muscle (SMCs) or stem cells. MGP indicates matrix Gla protein; and OPN, osteopontin. calcification, pointing toward the relevance of MGP in medial calcification.\textsuperscript{55,56}

The molecular mechanisms are different between intimal and medial calcification, and vascular intimal calcification is now considered an active process and that many nonmutually exclusive mechanisms exist.\textsuperscript{54,57} There is little consensus on which mechanisms of atherosclerotic intimal calcification apply best to humans. There seem to be different schools of thought raising 4 nonmutually exclusive concepts (Figure 8), with those who foster the idea that SMCs acquire an osteogenic profile and calcification occurs akin to bone formation. It is thought that extracellular vesicles (matrix vesicles) calcify when calcium phosphates appear inside these matrix vesicles, forming hydroxyapatite crystals, akin to bone formation.\textsuperscript{59} Apoptotic cell death generated form SMCs and macrophages calcify in the extracellular environment, and that nucleate hydroxyapatite mineral crystallization occurs.\textsuperscript{59} Within this group, there are those of us who believe in the concept that chronic low levels of SMC and macrophage apoptosis is the main driver of calcification in humans. Another concept is related to the loss of inhibitors of calcification molecules which are normally expressed in the vessel wall, such as MGP, osteopontin, fetuin, pyrophosphates, and others, that may lead to spontaneous calcification. Fetuin, a circulating glycoprotein, is a major inhibitor of apatite found in circulation, and decrease in fetuin levels results in augmented vascular calcification and higher cardiovascular mortality in hemodialysis patients. Also, the presence of bone proteins in the vessel wall, such as osteopontin, osteocalcin, and BMP-2, and the presence of bone and cartilage in vessel walls suggest osteogenic origin. Indeed, it has been shown in culture studies that SMCs phenotypically change to cartilage and bone and calcify under various conditions, and this view of calcification is being presented by Demer et al\textsuperscript{al} in this editorial series on calcification. The cell death view, along with other investigators such as Clarke et al,\textsuperscript{al} Kockx et al,\textsuperscript{al} and Proudfoot et al,\textsuperscript{al} is more in keeping with our observations in humans.

Roijers et al\textsuperscript{al} reported that microcalcification was occasionally observed in AIT and that there was abundant increase in microcalcification in American Heart Association type II, III, and IV lesions, that is, fatty streak, PIT, and fibroatheroma. They also showed that microcalcification preceded the presence of calcifying proteins such as osteocalcin and BMP-2. However, when these proteins were absent, other proteins such as uncarboxylated MGP were observed, which is released as biologically inactive precursor and thought to play an important role in the inhibition of calcification. Because of a delay to active form, that is, its carboxylation remains blocked during the course of atherosclerosis and likely results in early calcification. Clarke et al\textsuperscript{al} have shown in in vitro studies that vascular SMC apoptosis accelerates calcification. Vascular SMC apoptosis physiologically occurs without consequences; however, failure to clear apoptotic cell bodies by phagocytes results in release of proinflammatory cytokines.\textsuperscript{62}

Lutgens et al\textsuperscript{al} have shown that low level of apoptosis is mostly seen in lesions of fibroatheroma, with or without surface defects (American Heart Association type IV, V, and VI lesions). In terms of localization, apoptosis was most predominant in the lipid core in type IV lesions and equally divided between lipid core and fibrous cap in type V lesions.\textsuperscript{63} Interestingly, in ruptured plaques, it was equally divided between lipid core, fibrous cap, and the area underlying the rupture. Kockx et al\textsuperscript{al} have shown that SMC apoptosis is rare in fatty streak lesions. If present, it mostly occurs in SMCs which are enclosed by a cage of thickened basement membrane, frequently within the deeper layers of the plaque (Figure 2). In keeping with this, the necrotic core of advanced atherosclerotic plaques is largely acellular indicating cell death which must have occurred earlier or enlargement of the necrotic core may be secondary to plaque hemorrhage.\textsuperscript{64} Surrounding the necrotic core, especially toward the luminal surface, there is a dense infiltration of macrophages and these also show changes of apoptosis.\textsuperscript{65} A significantly greater number of apoptotic bodies have been identified within the necrotic core as compared with other parts of the plaque.\textsuperscript{66} Low-level apoptosis has been shown by Clarke et al\textsuperscript{al} to accelerate calcification in SM22α-human diphtheria toxin receptor apolipoprotein E–deficient mice promoting calcification in early and in late vulnerable plaques. It is not only apoptosis that is necessary, but also the calcification must occur at these sites of necrosis. Proudfoot et al\textsuperscript{al} showed in a culture model that SMC nodules calcify at sites of apoptosis and that this can be prevented by inhibiting apoptosis. Similarly, others have shown that calcification is enhanced after induction of hyperphosphatemia or addition of transforming growth factor–β1 in interstitial aortic valve cells.\textsuperscript{67,68} It is clear that calcium and phosphate ions in biological fluids are tightly regulated, and any abnormality as in chronic renal failure results in higher rates of calcification in soft tissues.

Although our understanding of atherosclerosis has progressed at the molecular level through the introduction of genetically engineered mouse models in the last few decades, there remain many unanswered questions, especially regarding the origin, mechanism, and purpose of calcification in human atherosclerosis. There has been tremendous progress in research related to the mechanisms of bone formation, which strongly supports the school of thought that vascular calcification may be akin to bone formation. Also, it has been shown in the mouse model that vascular SMCs undergo osteochondrogenesis and contribute to atherosclerotic intimal calcification.\textsuperscript{69} However, looking at this topic from a more observational point of view, vascular calcification is largely observed in areas of cell death. Data showing viable SMCs that do not calcify have been shown in culture studies. Reynolds et al\textsuperscript{al} have shown that the matrix around the SMCs calcifies, the cells remained viable, and once the calcified matrix is removed, they proliferate, thus showing viability of the SMCs.\textsuperscript{71} In addition, true lacunar bone formation including osteoblasts and osteoclasts in coronary atherosclerosis remains exceptional to our knowledge. Also, presence of cartilage has only rarely been reported in peripheral arteries, whereas reports inferring the existence of cartilaginous metaplasia in coronary lesions are lacking to date. From a pathological standpoint, vascular calcification seems to constitute a destructive event in advanced atherosclerotic lesions. Statin treatment has been shown to at least halt disease progression with respect to cholesterol accumulation in the vessel wall. Surprisingly, statin treatment has been reported to even increase calcification of atherosclerotic lesions, thus suggesting that calcification may be a marker of stable, nonprogressive atherosclerosis process.\textsuperscript{73} It could also
be that location of calcification is the most important and that small calcifications in the thin fibrous cap may contribute to plaque rupture. It is clear that large calcification located near the intimal-medical border does not impart instability to a plaque but may even be harbingers of stability. Novel imaging modalities, both invasive and noninvasive, will likely result in better understanding of calcification dynamics in the future.

Conclusions

Despite the undoubted association between coronary atherosclerotic calcification and prediction of future cardiovascular events, there is only weak correlation between calcification-induced coronary plaque progression and luminal narrowing. Coronary calcification is reported to occur sporadically in AIT/fibrous plaques and is almost uniformly seen in PIT with or without macrophages. In PIT lesions, calcification can be observed microscopically as microcalcification which is usually 0.5 to 15 μm in size and enlarging to ≥15 μm in early fibroatheromas, when macrophages infiltrate the necrotic core and undergo apoptosis. Confluent calcified areas begin to appear in fibroatheromas and occasionally in PIT and fibrous lesions. Calcified areas are mostly located around the necrotic core close to the media. In the course of atherosclerosis progression, calcified areas enlarge to form calcified sheets, which are hallmarks of stable plaques but may even be harbingers of stability. Novel imaging modalities, both invasive and noninvasive, will likely result in better understanding of calcification dynamics in the future.

Disclosures

None.

References

Intimal atherosclerotic calcification is the most common form of calcification, begins early, and is first appreciated in pathological intimal thickening when it can only be identified by special stains. It progresses from microscopic specking to punctate lesion accompanied by apoptosis of smooth muscle cells and macrophages and release of matrix vesicles. These microcalcified areas coalesce with eventual formation of fragments of calcification seen in fibroatheromas. The fragmented calcified areas are located close to the medial wall and extend to involve the necrotic core and the adjacent collagen eventually forming calcified sheets. Calcification is significantly greater in men than in women and correlates with plaque area but not with lumen area. It is only at this stage when calcified fragments reaches a threshold of 1.03 to 1.37 mm² in size that computed tomography can identify calcification. Computed tomography imaging techniques have shown that individuals with a high calcium score have a higher risk of developing future cardiovascular events.

**Significance**
