Associations of Plasma Kynurenines With Risk of Acute Myocardial Infarction in Patients With Stable Angina Pectoris

Eva Ringdal Pedersen, Nora Tuseth, Simone J.P.M. Eussen, Per Magne Ueland, Elin Strand, Gard Frodahl Tveitevåg Svingen, Øivind Midttn, Klaus Meyer, Gunnar Mellgren, Arve Ulvik, Jan Erik Nordrehaug, Dennis W. Nilsen, Ottar Nygård

Objective—Enhanced tryptophan degradation, induced by the proinflammatory cytokine interferon-γ, has been related to cardiovascular disease progression and insulin resistance. We assessed downstream tryptophan metabolites of the kynurenine pathway as predictors of acute myocardial infarction in patients with suspected stable angina pectoris. Furthermore, we evaluated potential effect modifications according to diagnoses of pre-diabetes mellitus or diabetes mellitus.

Approach and Results—Blood samples were obtained from 4122 patients (median age, 62 years; 72% men) who underwent elective coronary angiography. During median follow-up of 56 months, 8.3% had acute myocardial infarction. Comparing the highest quartile to the lowest, for the total cohort, multivariable adjusted hazard ratios (95% confidence intervals) were 1.68 (1.21–2.34), 1.81 (1.33–2.48), 1.68 (1.21–2.32), and 1.48 (1.10–1.99) for kynurenic acid, hydroxykynurenine, anthranilic acid, and hydroxyanthranilic acid, respectively. The kynurenines correlated with phenotypes of the metabolic syndrome, and risk associations were generally stronger in subgroups classified with pre-diabetes mellitus or diabetes mellitus at inclusion (P_int ≤ 0.05). Evaluated in the total population, hydroxykynurenine and anthranilic acid provided statistically significant net reclassification improvements (0.21 [0.08–0.35] and 0.21 [0.07–0.35], respectively).

Conclusions—In patients with suspected stable angina pectoris, elevated levels of plasma kynurenines predicted increased risk of acute myocardial infarction, and risk estimates were generally stronger in subgroups with evidence of impaired glucose homeostasis. Future studies should aim to clarify roles of the kynurenine pathway in atherosclerosis and glucose metabolism. (Arterioscler Thromb Vasc Biol. 2015;35:455-462. DOI: 10.1161/ATVBAHA.114.304674.)

Key Words: acute myocardial infarction • atherosclerosis • diabetes mellitus • epidemiology • inflammation • insulin resistance • tryptophan

Diabetes mellitus (DM) type 2 is a major risk factor for coronary artery disease (CAD) and both DM and CAD are characterized by chronic low-grade inflammation.\(^1\)\(^2\) T lymphocytes and macrophages contribute actively to the growth and disruption of atherosclerotic plaques and hence to clinical manifestations such as acute myocardial infarction (AMI).\(^3\) Moreover, inflammatory cells within adipose tissue mediate insulin resistance,\(^4\) an early feature in the progression from normoglycemia to overt type 2 DM.\(^4\)

The proinflammatory cytokine, interferon-γ (IFN-γ), is released from activated CD4\(^+\) T cells.\(^5\) IFN-γ induces indoleamine 2,3-dioxygenase, which is the rate-limiting enzyme of the kynurenine (Kyn) pathway.\(^6\) Through this route, the essential amino acid tryptophan (Trp) is metabolized into Kyn and several downstream metabolites, collectively referred to as kynurenines. Hence, the Kyn:Trp ratio (KTR) is an established marker of IFN-γ–mediated (Th1) immune responses.\(^7\)

Previously, we have shown that elevated plasma levels of KTR and an alternative IFN-γ marker, neopterin, were associated with unfavorable prognosis in patients with stable angina pectoris\(^8\) as well as in healthy, elderly adults.\(^9\) Moreover, we identified urine KTR as a particularly strong predictor of coronary events and mortality after elective coronary angiography.\(^10\)

The degradation of Kyn occurs through multiple steps, several of which use vitamin B\(_6\) as a cofactor (Figure 1).
Experimental studies suggest that dysregulation of the Kyn pathway may be involved in the pathogenesis of both CAD and DM. However, Trp catabolites other than Kyn have been related only to a limited extent to clinical outcomes in humans, and there is a paucity of data from large-scale epidemiological studies. Thus, we evaluated plasma levels of kynurenines in a prospective cohort of patients with suspected stable angina pectoris. In particular, we were interested in whether any associations with adverse prognosis were modified by evidence of impaired glucose homeostasis.

**Materials and Methods**

Materials and methods are available in the online-only Data Supplement.

**Results**

For the 4122 patients in the current study, median (25th–75th percentile) age at inclusion was 62 (55–70) years and 2967 (72.0%) were men. According to the most recent diagnostic criteria, 1603 (38.9%) had DM, of which the vast majority (97.4%) was classified with type 2 (n=1566). However, only a subset was prescribed antidiabetic medications (Table 1). All together, 1078 (25.9%) of patients were current smokers, 1935 (46.9%) had hypertension, and 1644 (40.4%) reported a prior AMI. Compared with the total population, median age and body mass index were higher in patients with DM, as were the prevalence of hypertension at inclusion and the incidence of AMI during follow-up (Table 1).

**Kynurenines and Baseline Characteristics**

Median values of all kynurenines were lower in women than in men (P<0.001). KA, HK, and AA were associated positively with age (ρ≥0.19; P<0.001), and except for HAA, kynurenines were higher in patients with DM as compared with subjects with normal glucose metabolism (Table 1). After adjustment for age and sex, median kynurenine-levels were uniformly lower in smokers than in nonsmokers and higher in hypertensive than in normotensive patients (all P<0.001). Plasma levels of kynurenines correlated positively with body mass index, serum creatinine, serum triglycerides, and plasma neopterin (Figure 2A). HK was positively correlated with C-reactive protein (CRP; ρ=0.25; P<0.001), whereas other kynurenines showed only weak or nonsignificant associations with this inflammation marker (Figure 2A). Plasma HAA correlated positively to nonfasting glucose (ρ=0.21; P<0.001). In contrast, neither metabolite was associated with glycosylated haemoglobin (HbA1c) levels (ρ≤0.04; P=0.06; Figure 2A).

However, in a subgroup of 593 fasting, nondiabetic patients, kynurenines were related to impaired insulin sensitivity, as evaluated by homeostatic model assessments of β-cell function and insulin resistance (Figure 2B). The strongest correlations were found for HAA (ρ=0.22 and ρ=0.34, respectively; P<0.001). Notably, such associations could not be demonstrated for the inflammation markers, neopterin or CRP (ρ≤0.07, P=0.09), and were only weak for the KTR (ρ≤0.08; P=0.04).

**Kynurenines and Risk of AMI in the Total Population**

During a median (25th–75th percentile) follow-up time of 56 (44–70) months, 8.3% (n=343) had AMI. Table I in the online-only Data Supplement shows the age- and sex-adjusted associations of kynurenines with risk of AMI. Multivariable hazard ratios (95% confidence interval) comparing the fourth to the first quartile of plasma concentrations were 1.68 (1.21–2.34) for KA, 1.81 (1.33–2.48) for HK, 1.68 (1.21–2.32) for AA, and 1.48 (1.10–1.99) for HAA (Table 2, left). These estimates were comparable with those of the established inflammation markers KTR (1.76 [1.27–2.45]) and CRP (1.45 [1.05–2.00]).

Adding creatinine or CRP to the multivariable model only minimally affected hazard ratios for the individual kynurenines (Tables II and III in the online-only Data Supplement, respectively). Adjustment for KTR somewhat attenuated the risk estimates, which, however, remained statistically significant (Table IV in the online-only Data Supplement). Plasma levels of xanthurenic acid showed no significant associations with AMI risk overall or in subgroups according to DM status (Table I in the online-only Data Supplement; Table 2).

**Figure 1.** Overview of the kynurenine pathway of tryptophan metabolism. FAD indicates flavin adenine dinucelotide (vitamin B2); IDO, indoleamine-2,3-dioxygenase; KAT, kynurenine aminotransferase; KMO, kynurenine-3-monooxygenase; KYNU, kynureninase; PLP, pyridoxal 5′-phosphate (vitamin B6); and TDO, tryptophan 2,3-dioxygenase.

Sensitivity Analyses

Because of the different routines for sample handling at the 2 study centers, separate Cox analyses were performed for patients included at Haukeland University Hospital (n=3384) and Stavanger University Hospital (n=738). Risk estimates were similar to those found in the whole data set (data not shown). Similarly, including adjustment for study center to the multivariable model did not affect the risk estimates for the total population (Table V in the online-only Data Supplement). There was no statistically significant interaction between study center and any of the kynurenines (P_int ≥0.17) in relation to AMI risk.

Kynurenines and Risk of AMI According to DM Status

We further investigated potential effect modifications according to DM status (Table 2, right; Figure I in the online-only Data Supplement). The associations of kynurenines with incident AMI were generally stronger in those classified with pre-DM or DM than in the subgroup without evidence of impaired glucose metabolism. Comparing quartile 4 versus quartile, hazard ratios (95% confidence interval) among patients with pre-DM were 2.51 (1.27–4.95), 2.24 (1.18–4.24), and 2.27 (1.20–4.33) for KA, AA, and HAA, respectively. In diabetics, the strongest risk estimate was found for HK (2.37 [(1.43–3.93)].

Goodness of Fit, Risk Reclassification, and Discrimination

Evaluated in the total population, the addition of KA, HK, AA, or HAA improved goodness of fit for the multivariable model (Table 3). HK and AA both provided significant net reclassification improvements (95% confidence interval) of 0.21 (0.08–0.35) and 0.21 (0.07–0.35), respectively. However, the increments in areas under receiver operator characteristic curves were modest and statistically significant for AA only (Table 3). These results were literally unchanged after including CRP to the multivariable model (Table VI in the online-only Data Supplement).

Among patients without DM, HK was the only metabolite improving model goodness of fit (P=0.03). With the exception of xanthurenic acid, all kynurenines provided significant reductions of Aikaikes’ Information Criteria values in patients with pre-DM (P≤0.05), whereas HK, AA, and HAA improved model fit in patients with DM (P≤0.01). Reclassification analyses showed similar results for AA and HK in stratified analyses as in the total population, with only weak tendencies toward numerically stronger estimates among patients with pre-DM or DM (net reclassification improvements, 0.20–0.28). In addition, HAA, which did not improve risk categorization in the total population, provided a net reclassification improvement (95% confidence interval) of 0.26 (0.06–0.49) among patients with pre-DM.

Among nondiabetic patients, the area under receiver operator characteristic curve for the multivariable model without individual kynurenines was 0.66. Each of the metabolites provided increases in areas in the range of 0.002 to 0.009. Corresponding estimates were 0.73 (increments by kynurenines, 0.009–0.026) and 0.74 (increments by kynurenines, 0.003–0.010) for patients with pre-DM and DM, respectively. In subgroup analyses, none of the increases in areas under the curves were statistically significant (P≥0.08), probably because of reduced power.

Discussion

Principal Findings

In patients with suspected stable CAD, downstream Trp metabolites of the Kyn pathway were associated with increased risk of incident AMI. Plasma kynurenines were generally higher in patients with DM than in subjects with normal glucose metabolism. Levels were associated with several components of the metabolic syndrome (hypertension, body mass index, and serum triglycerides) but showed only weak or no correlations to CRP, glucose, or HbA1c values. Notably, the associations with adverse outcome remained significant after adjustment for potential confounders. Moreover, risk estimates were significantly higher in patients with evidence of impaired glucose homeostasis at baseline.
Kynurenines, Atherosclerosis, and Insulin Resistance

Similar to our findings among patients with stable angina pectoris, associations of kynurenines with CAD risk factors have been reported in presumably healthy populations. HK correlated with intima media thickness of the carotids. Moreover, HK and KA were both associated with the presence of cardiovascular disease in patients with renal failure. Interestingly, a recent metabolomics study reported correlations of kynurenines with components of the metabolic syndrome and hypothesized these metabolites to be involved in the pathogenesis of insulin resistance. To the best of our knowledge, the associations of kynurenines with CAD risk factors have been reported in presumably healthy populations. HK correlated with intima media thickness of the carotids.

HRs are presented per quartile increment and for quartile 4 (Q_4) vs quartile 1 (Q_1) of the respective biomarkers. AA indicates anthranilic acid; CI, confidence interval; HAA, hydroxyanthranilic acid; HK, hydroxykynurenine; HR, hazard ratio; KA, kynurenic acid; and XA, xanthurenic acid.

*Adjusted for age, sex, body mass index, hypertension, diabetes mellitus, smoking, angiographic extend of coronary artery disease, apoA1, and apoB.
apoA1 and apoB.

Effects on our risk estimates. Hence, the associations of kynurenines with outcomes seem not solely to reflect pathways activated in renal dysfunction.

Individual kynurenines inhibited proinsulin synthesis from pancreatic islets in rat models and formed complexes with insulin reducing its biological activity. Impaired insulin sensitivity may be present years before the occurrence of overt hyperglycemia and is associated with increased risk of macrovascular disease even in the absence of type 2 DM.

Impaired endothelial function represents a common feature of atherosclerosis, renal dysfunction, and insulin resistance and is characterized by decreased NO-mediated vasodilatation of arteries. Oxidative stress is a key pathogenic factor. In an environment with overload of free radicals, arginine metabolism is shifted from NO synthesis toward the production of superoxide anion in a self-perpetuating process. HK and HAA potentially contribute to this process by promoting lipid peroxidation as well as by inhibiting NO synthase. Conversely, peroxynitrite, formed from NO during oxidative stress, is able to bind and inactivate the indoleamine-2,3 deoxygenase enzyme. Moreover, Kyn has been identified as a potent, NO-independent, vasodilator. Vascular protective effects have also been revealed for KA. Hence, evidence suggests that Trp degradation has diverse and complex effects on inflammatory pathways, metabolism, and the vasculature.

AA indicates anthranilic acid, AIC, Akaike’s Information criteria; CI, confidence interval; HAA, hydroxyanthranilic acid; HK, hydroxykynurenine; KA, kynurenic acid; NRI, net reclassification improvement; and ROC-AUC, area under receiver operator characteristics curve.

Possible Mechanisms

The expression of genes related to Kyn metabolism was upregulated in atherosclerotic plaques. Further, Trp degradation was increased in fat tissues and liver of obese as compared with lean women, supporting a role of this metabolic pathway in CAD and other obesity-associated pathologies.

In the present study, downstream kynurenines were strongly correlated with KTR, an established marker of IFN-γ activity and Th1 immune responses. Notably, their risk estimates remained statistically significant even after adjustment for plasma KTR levels. Hence, the associations with incident AMI seem not solely to reflect IFN-γ activation per se but may suggest independent pathogenic roles of the downstream metabolites.

Trp catabolism is considered to be centrally involved in balancing activation and inhibition of the immune system. In a mouse model, treatment with HAA reduced atherosclerotic lesions in the aorta, modulated local as well as systemic inflammatory responses, and lowered lipoprotein levels.

This metabolite and other kynurenines were also identified as endogenous ligands of the transcription factor aryl hydrocarbon receptor known to mediate vascular inflammation and procoagulant effects.

Our findings of positive correlations of kynurenines to creatinine are in line with previous publications and possibly reflect the combination of increased synthesis because of inflammatory activation and reduced renal clearance in patients with chronic kidney disease. Indeed, Trp metabolism has been hypothesized as a causal mechanism contributing to accelerated atherosclerosis in renal disease. Notably, however, adjustment for serum creatinine levels had only minor implications on our risk estimates. Hence, the associations of kynurenines with outcomes seem not solely to reflect pathways activated in renal dysfunction.

Individual kynurenines inhibited proinsulin synthesis from pancreatic islets in rat models and formed complexes with insulin reducing its biological activity. Impaired insulin sensitivity may be present years before the occurrence of overt hyperglycemia and is associated with increased risk of macrovascular disease even in the absence of type 2 DM.

Impaired endothelial function represents a common feature of atherosclerosis, renal dysfunction, and insulin resistance and is characterized by decreased NO-mediated vasodilatation of arteries. Oxidative stress is a key pathogenic factor. In an environment with overload of free radicals, arginine metabolism is shifted from NO synthesis toward the production of superoxide anion in a self-perpetuating process. HK and HAA potentially contribute to this process by promoting lipid peroxidation as well as by inhibiting NO synthase. Conversely, peroxynitrite, formed from NO during oxidative stress, is able to bind and inactivate the indoleamine-2,3 deoxygenase enzyme. Moreover, Kyn has been identified as a potent, NO-independent, vasodilator. Vascular protective effects have also been revealed for KA. Hence, evidence suggests that Trp degradation has diverse and complex effects on inflammatory pathways, metabolism, and the vasculature.

Figure 3. Dose–response relationship between plasma kynurenines and risk of acute myocardial infarction for the total population. The regression models are adjusted for age, sex, body mass index, hypertension, smoking, diabetes mellitus, apoA1, apoB, and angiographic extent of coronary artery disease. The solid lines show the hazard ratios and the shaded areas 95% confidence intervals. Density plots show the distributions of plasma kynurenines and vertical lines denote the 10th, 25th, 50th, 75th, and 90th percentiles.
The correlations of kynurenines to the homeostatic model assessment of insulin resistance support previous studies linking Trp degradation to impaired insulin sensitivity.\(^7\) Interestingly, similar associations were also observed for several branched amino acids.\(^3\) Our findings thus possibly mirror a more generalized derangement of amino acid metabolism in the insulin-resistant state.\(^9\) Hence, despite extensive experimental data suggesting kynurenines as potential active mediators, it is still unclear whether elevated plasma levels reflect causal pathways or only epiphenomena of disease development.

Several single nucleotide polymorphisms for genes of the Kyn pathway are identified.\(^3,4\) To the best of our knowledge, such genetic variants have not been related to cardiovascular or diabetic outcomes in humans. Future Mendelian randomization studies may extend current knowledge on causality. This may be of particular value because the Kyn axis can eventually be targeted by lifestyle\(^6\) or medical\(^25\) intervention.

**Strengths and Limitations**

Strengths of the study include its prospective design and large sample size. We had detailed data on clinical baseline characteristics including parameters of glucose metabolism as well as the angiographic extent of CAD. Follow-up was ascertained through the use of a patient administrative and a population-based registry. We cannot exclude the possibility that the report of clinical end points has been subjected to some under-reporting or other misclassification. However, we do not suspect that any misclassifications differ according to the levels of kynurenines.

The homeostatic model assessments of insulin resistance and β-cell activity could only be calculated reliably in a subgroup reporting to be fasting at the time of blood sampling. Further limitations of our study include potential bias introduced by the single measurement of biomarkers. Although HbA1c has low intrindividual variability,\(^7,8\) current guidelines recommend glucose or HbA1c to be determined at 2 separate occasions for the diagnosis of DM.\(^9\) Notably, a prior publication from our group demonstrated that all kynurenines have sufficient within-person reproducibility to allow 1-exposure assessment in epidemiological studies.\(^40\)

The significant associations of kynurenines with AMI risk persisted even after extensive multivariable adjustment. However, improvements in risk classifications by these metabolites were only moderate in the total population as well as in subgroups with impaired glucose homeostasis. Hence, it remains to be determined whether their measurements can be justified in clinical practice. Our data nonetheless provide epidemiological support to experimental studies linking Kyn pathway activation to atherosclerotic complications and insulin resistance.

**Conclusions**

In patients with suspected stable angina pectoris, downstream metabolites from the Kyn axis predicted increased risk of AMI independently of traditional risk factors. Individual kynurenines correlated with phenotypes of the metabolic syndrome, and the associations with adverse prognosis were generally stronger among patients with evidence of impaired glucose homeostasis. The roles of Trp degradation in CAD progression and energy metabolism should be further elucidated, as it potentially represents a novel interventional target.\(^25,36\)

Increased tryptophan degradation induced by the proinflammatory cytokine interferon-γ has been related to coronary artery disease and pathogenic roles of tryptophan catabolism in lifestyle-related diseases. Over, risk estimates were generally higher in subgroups with evidence of impaired glucose homeostasis at baseline. Our findings support myocardial infarction independently of traditional risk factors. The kynurenines correlated with phenotypes of the metabolic syndrome. Moreover, estimations were generally higher in subgroups with evidence of impaired glucose homeostasis at baseline. Our findings support myocardial infarction independently of traditional risk factors. The kynurenines correlated with phenotypes of the metabolic syndrome.

Significance

Increased tryptophan degradation induced by the proinflammatory cytokine interferon-γ has been related to coronary artery disease and insulin resistance. We evaluated downstream tryptophan metabolites from the kynurenine pathway in a large-scale prospective cohort study. Among ~4000 patients with stable angina pectoris, followed up for >4 years, plasma levels of several kynurenines predicted incident acute myocardial infarction independently of traditional risk factors. The kynurenines correlated with phenotypes of the metabolic syndrome. Moreover, risk estimates were generally higher in subgroups with evidence of impaired glucose homeostasis at baseline. Our findings support experimental studies linking the kynurenine pathway to atherogenesis and insulin resistance and strongly encourage further research into pathogenic roles of tryptophan catabolism in lifestyle-related diseases.
Associations of Plasma Kynurenines With Risk of Acute Myocardial Infarction in Patients With Stable Angina Pectoris

Material and Methods

Study Population
The source population has been described in detail elsewhere. Briefly it consists of 4164 adults who underwent elective coronary angiography for suspected stable angina pectoris in the period 2000-2004. Patients were recruited from Haukeland (n=3413) or Stavanger (n=751) University Hospitals in Norway. A total of 2573 (61.8%) were subsequently included in the Western Norway B Vitamin Intervention Trial (ClinicalTrials.gov Identifier: NCT00354081). Patients with missing data on glycated haemoglobin (HbA1c) at baseline were excluded (n=42), leaving 4122 participants eligible for the final analyses. The study fulfilled the Declaration of Helsinki; and was approved by The Western Norway Regional Committee for Medical and Health Research Ethics (approval number 2010/1880) and the Norwegian Data Protection Authority. Written informed consents were obtained from all subjects.

Baseline Data
Information about medical history, cardiovascular disease risk factors and medications were collected from self-administered questionnaires and validated against medical records. Prediabetes was defined as HbA1c of 5.7-6.4% according to the American Diabetes Association (ADA) guidelines. Diabetes mellitus included both type 1 and 2 and was defined by fasting plasma glucose ≥7mmol/l, non-fasting plasma glucose ≥11.1mmol/l or HbA1c ≥6.5%. Hypertension was defined by pre-existing diagnosis. Body mass index (BMI) was calculated by dividing weight by height squared (kg/m²). Fasting referred to not having ingested any food or beverage 6 hours prior to blood sampling. Left ventricular ejection fraction (LVEF), angiographic extent of coronary artery disease and smoking status were assessed as previously reported.

Follow-up and Clinical End Points
Patients were followed from the time of the first coronary angiography in 2000-2004, until suffering from an acute myocardial infarction (fatal or nonfatal), or through December 31, 2006. Details on the routines for collection and classification of clinical endpoints have been described previously.

Biochemical Analyses
Baseline venous samples from patients recruited at Haukeland University Hospital were drawn 1-3 days before the coronary angiography and were immediately frozen at -80° C until analyzed in 2007-2008. Samples collected from Stavanger University Hospital were taken after the angiographic procedure and were subsequently transported to the core laboratory, resulting in a delay of maximum 48h, until separation and storage at -80° C. All study specific analyses were performed by Bevital AS, Bergen, Norway (www.bevital.no) by laboratory personnel who were blinded to the clinical outcomes of patients. C-reactive protein (CRP) was measured in serum using an ultrasensitive immunoassay, Behring nephelometer II system N Latex CRP mono (Behring Diagnostics, Marburg, Germany). Serum levels of apolipoprotein A1 and apolipoprotein B were measured on Hitachi 917 and 912 systems (Roche Diagnostics, GmbH, Mannheim, Germany), respectively. Plasma concentrations of tryptophan, kynurenines, and pyridoxal phosphate (vitamin B6) were analysed by liquid chromatography/tandem mass spectrometry.
HbA1c was determined by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry.6

Among 593 (14.3%) fasting, non-diabetic patients we also calculated the homeostatic model assessments7 of insulin resistance, β-cell function and insulin sensitivity, based upon serum insulin, which was measured together with serum C-peptide in citrate-based samples by a solid phase, two-site chemiluminescent immunometric assay (Immulate 2000 C-Peptide) from Siemens Health Care Diagnostic.

**Statistical Analyses**

Continuous variables are reported as medians (25th-75th percentiles) and categorical variables as counts (percentages). Differences in baseline characteristics across categories of clinical variables were assessed by linear median regression for continuous variables and logistic regression for categorical variables. Associations between continuous variables were evaluated by Spearman rank correlation, adjusted for age and gender. Hazard ratios and 95% confidence intervals for acute myocardial infarction were calculated using Cox regression and are reported per quartile increment of plasma kynurenines. The simple model included age and gender as independent variables. Additional covariates for the multivariable model were selected on the basis of clinical relevance and included: BMI (kg/m²), hypertension (yes versus no), smoking status (current smoking; yes versus no), diabetes status (no diabetes versus prediabetes/diabetes), angiographic extent of coronary artery disease (0-3) and serum levels of apolipoprotein A1 (g/L) and apolipoprotein B (g/L). Further adjustments for fasting status, serum creatinine, serum triglycerides, serum CRP, plasma pyridoxal phosphate or study centre did not appreciably alter the results and were not included in the final model. We performed log-log plots and plotted Schoenfeld residuals to ensure that the assumption of proportional hazards was not violated.8 Effect modifications were tested by adding interaction product terms to the models.

Non-linear associations between kynurenines and risk of acute myocardial infarction were visualized by generalized additive regression plots,9 in which individual metabolites were modelled with a 4 degrees of freedom smoothing spline fit in multivariable Cox regression models. Model fit was compared using the Akaike’s information criterion. We explored model discrimination by calculating areas under receiver operator characteristics curves with and without individual kynurenines added to the multivariable Cox model. By determining continuous net reclassification improvement (NRI >0),10 we evaluated whether any of the metabolites could assign a substantial number of participants into a more correct level of risk. For the NRI analyses we applied logistic regression models, containing the same variables as the Cox models, in which follow-up was censored beyond 1000 days, roughly corresponding to the minimum follow-up time. All reported probability values are two-tailed and were considered significant when <0.05. Statistical analyses were performed using SPSS (version 21 for Macintosh, Chicago, IL) and R11 (version 3.1.1 for Macintosh).
