ABO Blood Group as a Model for Platelet Glycan Modification in Arterial Thrombosis

Ming Zhong, Hanrui Zhang, John P. Reilly, Jason D. Chrisitie, Mayumi Ishihara, Tadahiro Kumagai, Parastoo Azadi, Muredach P. Reilly

Abstract—ABO blood groups have long been associated with cardiovascular disease, thrombosis, and acute coronary syndromes. Many studies over the years have shown type O blood group to be associated with lower risk of cardiovascular disease than non–type O blood groups. However, the mechanisms underlying this association remain unclear. Although ABO blood group is associated with variations in concentrations of circulating von Willebrand Factor and other endothelial cell adhesion molecules, ABO antigens are also present on several platelet surface glycoproteins and glycosphingolipids. As we highlight in this platelet-centric review, these glycomic modifications may affect platelet function in arterial thrombosis. More broadly, improving our understanding of the role of platelet glycan modifications in acute coronary syndromes may inform future diagnostics and therapeutics for cardiovascular diseases. (Arterioscler Thromb Vasc Biol. 2015;35:1570-1578. DOI: 10.1161/ATVBAHA.115.305337.)

Key Words: ABO blood-group systems ■ acute coronary syndrome ■ blood platelets ■ glycoproteins ■ thrombosis

Cardiovascular disease (CVD), including coronary artery disease (CAD), cerebrovascular disease, and peripheral vascular disease, is a leading cause of morbidity and mortality throughout the world and the United States. According to the American Heart Association, CVD accounted for 31.9% of all mortality within the United States in 2010, with 1 of every 6 deaths attributable to CAD.1 Despite some success in reducing rates of heart disease, these realities demand new innovations to CAD prevention and novel therapeutic strategies.

Vascular inflammation, driven by hyperlipidemia and diverse risk factors, promotes leukocyte recruitment and transmigration to the subendothelium, mediated in large part by adhesion molecules, chemokines, and cytokines expressed on endothelial cells and leukocytes.2 Once atherosclerotic lesions have developed, physical and inflammatory disruption of these plaques incites a platelet-dependent thrombosis and acute coronary syndrome (ACS).

An active area of research is the role of the ABO blood group locus and glycosyltransferases in the pathophysiology of CAD and ACS. A multitude of studies has shown an association between non-O blood groups and both prevalence and incidence of CAD,3,4 as well as increased mortality in patients with ischemic heart disease;5 and size of myocardial infarction (MI) during ACS.6 The mechanism behind the association of ABO blood type and CVD has been studied but not yet clearly elucidated. One potential mechanism is that ABO glycosyltransferases modify platelet surface glycoproteins and glycolipids, resulting in terminal modifications that impact the function of platelets. Understanding the ways in which ABO glycans modulate platelet glycoprotein and glycolipid function with respect to platelet activation, aggregation and platelet-driven thrombosis may improve our knowledge of the mechanisms underlying arterial thrombosis and ACS. Thus, this review will examine the existing knowledge of ABO blood group effects on CAD and ACS with a specific focus on the potential impact of ABO on platelet function and arterial thrombosis, while also considering more broadly the impact of diverse glycomic modifications on platelet function and biology.

ABO Blood Group, Thrombosis, and ACS

ABO blood group phenotype is determined by the expression of specific antigens on red blood cells, endothelial cells, platelets, and many other cells and tissues. The presence of A or B antigen results in the expression of A, B, or AB phenotype, whereas the lack of both A and B antigen results in the expression of the O phenotype. These ABH antigens comprise complex terminal carbohydrate molecules on glycoproteins and glycolipids, generated by the addition of N-acetylgalactosamine (A antigen) or α-galactose (B antigen) to existing N-glycan and O-glycan structures through the action of the ABO glycosyltransferases.7 The A and B alleles of the ABO locus encode A and B glycosyltransferases, which in turn catalyze the transfer of the different carbohydrates onto a common core H antigen, to form an A or

1570
B antigen. However, type O individuals only express H antigen because the O isoform of ABO lacks glycosyltransferase activity.8

In the past, studies have associated ABO blood groups with CVD, whereby non–type O blood groups are associated with higher risk of CVD, MI, and thrombosis than type O blood group.3 Previous genome-wide association studies (GWAS) have also identified associations between ABO blood type and cardiovascular risk factors, such as serum cholesterol and low-density lipoprotein,9 implying a role of ABO blood type in atherogenesis. However, GWAS also have highlighted that the top common genetic polymorphisms associated with MI, in the setting of known angiographic CAD, map to the ABO blood group locus.10 This finding is distinct from other GWAS for more generally defined CAD phenotypes,10,11 which reflect the association with coronary atherosclerosis but not necessarily ACS and MI per se. The same ACS/MI ABO locus variants also associate with venous thrombosis. Thus, these human genetic findings implicate ABO genotype as a potential effector not only for atherogenesis but also in the pathophysiology of thrombosis, as well as ACS and MI in the presence of existing coronary atherosclerosis.

One proposed mechanism to explain the increased risk of coronary thrombosis in non–blood group O individuals is that ABO A and B glycotransferases modulate levels of circulating von Willebrand factor (VWF), where non-O blood group individuals have higher plasma levels, which is in turn is associated with greater risk of venous and arterial thrombosis.12 VWF modulates thrombosis by promoting subendothelial collagen interactions with platelet glycoprotein Ib/IIa and is also directly complexed with factor VIII in circulation. Circulating VWF is known to express ABH antigenicity,12,13 where the amount of H antigen expressed influences serum concentrations of VWF.14 Non–blood group O individuals have ≈25% higher plasma levels of VWF than O individuals.15 Much of this variation has been attributed to differences in clearance of VWF, as opposed to synthesis, across different blood groups. Gallinaro et al16 showed that O blood group individuals had significantly faster clearance of VWF than non-O individuals, where the elimination half-life of VWF in O versus non-O groups was 10.0±0.8 hours versus 25.5±5.3 hours, respectively, P<0.01. Work by Bowen17 suggests that differences in VWF clearance across blood groups might be secondary to differences in rates of proteolysis of VWF by ADAMTS13 (A Disintegrin and Metalloproteinase with Thrombospondin motifs), where the O group had significantly higher rates of proteolysis than non-O groups. This difference in susceptibility to proteolysis seems to be related to the presence of A or B antigens and the addition of terminal sugars on VWF glycoproteins, as well as the presence or absence of the H antigen.18 Furthermore, ABO blood groups have also been associated with serum levels of the procoagulating factor, factor VIII, with non-O individuals having ≈25% higher levels than blood group O carriers.13 The Cohorts for Heart and Aging Research in Genome Epidemiology Consortium GWAS did not find any ABO polymorphisms associated with factor VIII levels independent of blood levels of VWF.19 These results imply that ABO’s association with serum factor VIII levels are likely attributable to VWF complexing with factor VIII in circulation.

Although ABO blood type is associated with circulating levels of VWF (single nucleotide polymorphisms that tag the ABO blood groups account for 15.4% of the log variance), there are several other mechanisms that regulate VWF concentration. Studies of healthy European cohorts have shown that VWF level varies depending on age, body mass, and common polymorphisms within the VWF gene.20 In addition, murine models have been developed with expression of both increased and decreased levels of VWF,21,22 despite the fact that mice do not express ABH antigenicity. At least part of this variance in VWF level is thought to be caused by differences in the level of VWF sialylation. This hypothesis was investigated by McGrath et al,13,23 where desialylated VWF was more prone to cleavage by serine and cysteine proteases, but less susceptible to cleavage by ADAMTS13 supporting the idea that similarly to ABO glycosylation, sialylation of VWF may alter its rate of clearance. In fact, the effect of sialylation may even be understated, as erythrocytes and platelets lose their sialic acid during blood banking via irreversible membrane alterations.24 Although it is unknown whether VWF loses sialic acid during sample banking, any tendency for ex vivo desialylation could make it more difficult to identify the specific targets of sialylation that ultimately impact VWF level.

Beyond associations with levels of circulating VWF, blood group phenotype is also thought to affect endothelial–leukocyte interactions and leukocyte recruitment and transmigration to inflamed endothelium by influencing serum levels of endothelial-derived adhesion molecules, including soluble P-selectin, E-selectin, and intercellular adhesion molecule-1. A large-scale GWAS by Barbalic et al suggested that both soluble P-selectin and soluble intercellular adhesion molecule-1 are associated with ABO polymorphisms, with lower levels of sP-selectin and soluble intercellular adhesion molecule-1 associated with A1 and A2 blood group alleles. Similarly, a GWAS by Paterson et al demonstrated that polymorphisms around the ABO locus are associated with soluble E-selectin levels, accounting for ≤19% of variability, with highest concentrations associated with type O blood group. Notably, the direction of ABO blood group association with blood levels of these endothelial-derived adhesion molecules is opposite to that for VWF. Yet, it remains unclear how blood adhesion molecule associations occur, ie, via glycan modifications that alter secretion,
cleavage, turnover, or clearance. Despite the association between blood group O and lower rates of cardiovascular events, blood group O carriers have higher levels of soluble P-selectin and soluble intercellular adhesion molecule-1. Yet higher concentrations of these adhesion molecules are actually associated with increased risk for cardiovascular events.25 One potential explanation for this confusing observation is that ABO phenotype affects the concentration of adhesions molecules differently during acute pathophysiology, such as ACS/MI compared with at rest. It is also possible that the function of adhesions molecules, in addition to the concentration, differs among ABO groups. Although these associations have been studied with soluble cell adhesion molecules, ABO glycans may also have an impact on levels or function of intracellular or membrane-bound adhesion molecules on endothelial cells, which play a direct role in leukocyte–platelet–endothelial interactions.

ABO blood group associations may promote ACS/MI in additional ways beyond the effect on serum concentrations of VWF and cell adhesion molecules via distinct modulation of plaque rupture, platelet-dependent thrombosis, or both. Although platelet counts do not differ by blood group,3–6 ABH antigens are expressed on both platelet membrane lipids and platelet glycoproteins, and these may influence platelet interactions with fibrinogen and VWF, thereby modulating platelet aggregation and platelet-driven thrombosis.

ABO Expression on Platelet Glycoproteins and Glycolipids

Platelet Glycoproteins

Blood type A and B carbohydrate antigens are expressed on platelet glycoproteins, including several glycoprotein antigens that play key roles in thrombotic pathways. Santos et al47 discovered the presence of ABH antigenicity on platelet glycoproteins IIa and IIIa, as well as the glycoprotein IIb/IIIa complex by utilizing anti-A and anti-B IgG antibodies and radioimmunoprecipitation. The glycoprotein IIb/IIIa receptor complex mediates platelet aggregation in ACS and MI via binding of fibrinogen, fibronectin, and VWF.28 The role of glycoprotein IIb/IIIa in arterial thrombosis has been highlighted by numerous studies showing the benefits of targeting the glycoprotein complex.29 Similarly, glycoprotein IIa is a part of the glycoprotein Ia/IIa complex, which binds collagen and stabilizes platelets to exposed collagen at sites of injured endothelium. It is possible that ABO modification of this glycoprotein complex may also impact its function and expression, thereby affecting platelet function in arterial thrombosis. Therefore, knowledge of the extent and exact locations of ABO modification of glycoproteins Ia/IIa and IIb/IIIa may provide additional insight into the mechanistic underpinnings of platelet aggregation and thrombosis in ACS and MI and also impact future drug therapies. ABH antigens are expressed on several other platelet glycoproteins, including glycoprotein Ib,30 glycoprotein IV, and glycoprotein V.31 Glycoproteins Ib and V are a part of the glycoprotein Ib–IX–V complex, which mediates platelet adhesion to injured endothelium via the binding of VWF and thereby initiates events leading to thrombosis.32 Platelet glycoprotein Ib–IX–V complex is proposed to play a significant role in arterial thrombosis during shear-induced binding of VWF in the setting of abnormal blood flow and shear at sites of atherosclerosis. This binding subsequently induces platelet activation and aggregation via the binding of thrombin and VWF to initiate the formation of a thrombus.33 ABH antigenicity is also expressed on platelet endothelial cell adhesion molecule-1 (PECAM-1).34 PECAM-1 is a glycoprotein expressed on the surface of platelets and endothelial cells and is thought to play a role in atherogenesis via leukocyte adhesion and transmigration.35 Yet, recent studies by Falati et al36 used PECAM-1–deficient mice to show that arteriole thrombi, induced by laser injury, were larger and formed more rapidly. Thus, PECAM-1 seems to be a negative regulator of platelet-driven thrombosis in vivo. ABO glycomic modifications of PECAM-1 may have a functional impact on platelet-driven thrombosis. Understanding the impact of these platelet-related glycan and glycoprotein modifications may inform future diagnostics and therapeutics, specifically targeting ABO-modified platelet glycoproteins.

One novel mechanism by which glycan modifications of platelet glycoproteins may alter platelet function is via galectin–glycan interactions. Galectins are a family of proteins, which specifically bind β galactosides, glycans, which can be bound to proteins via N-linked or O-linked glycosylation.37 Galectins are expressed both extracellularly, in circulation and within extracellular matrices, and intracellularly within the nucleus, cytoplasm, and outer plasma membrane. Furthermore, galectins are expressed within a variety of tissue, including endothelial, epithelial, and adipose tissue. There have been 15 unique galectins discovered although only 12 are present in humans, where different galectins can recognize different glycan structures and with different affinities. Galectins Gal-1 and Gal-8 can act as potent platelet agonists, inducing both platelet aggregation via a conformational change of glycoprotein IIb/IIIa38,39 and platelet adhesion to an extracellular matrix. These galectins are able to mediate their effects on platelets by interacting with specific platelet surface glycans expressed on glycoproteins. Gal-8 binds platelet surface glycoprotein Ib and glycoprotein IIB, whereas the exact targets for Gal-1 are still unknown.39 It is possible that ABO glycan modifications could affect how platelet glycoproteins interact with their respective galectins, thereby affecting platelet activation, adhesion, and aggregation.

Platelet Glycolipids

Platelet glycosphingolipids also play a prominent role in platelet activation, aggregation, and thrombosis40–42 by modulating transmembrane signal transduction. These glycosphingolipids affect platelet function by interacting with various cell adhesion molecules such as P-selectin, fibrinogen, and VWF. In a study by Merten, sulfatide, a sulfated glycosphingolipid, was found to affect platelet adhesion by acting as a ligand to P-selectin, where exposure to a sulfatide antagonist decreased the extent of platelet adhesion.43 Guclukhan et al44 further illustrated the role of sulfatide, by exposing platelets to a sulfatide antibody probe. By blocking sulfatide, they inhibited platelet
adhesion to P-selectin, fibrinogen, and VWF. In addition, there was decreased platelet aggregation to agonists collagen, ADP, and thrombin, suggesting that sulfatide may also play a role in the formation of stable platelet aggregates. Indeed, in sulfatide-deficient mice, there was a longer time to in vitro platelet aggregation with collagen compared with that in wild-type mice.

Beyond sulfated glycosphingolipids, platelet surfaces express many neutral glycosphingolipids and sialylated glycosphingolipids, known as gangliosides, with the most abundant being hematoside (GM3), globoside, and trihexosylceramide. These platelet surface glycosphingolipids and gangliosides undergo both quantitative and qualitative changes during platelet activation, thereby affecting platelet adhesion and aggregation. Wang and Schick demonstrated that exposure of platelets to thrombin reduces by ≈50% the surface labeling of trihexosylceramide and globoside, while increasing hematoside surface labeling. Resting platelets predominantly express the ganglioside GM3 yet platelet activation by ADP, collagen, or arachidonic acid increased surface expression of GD3, suggesting that GD3 serves as a messenger in platelet adhesion and activation. Activation of platelets by thrombin receptor agonist peptide increases expression of sulfated glycosphingolipids on the platelet surface. Furthermore, the addition of micelles containing sulfated glycosphingolipids inhibited platelet adhesion to P-selectin. In contrast, antagonists of sulfated glycosphingolipids reduced ADP and thrombin receptor agonist peptide-induced platelet aggregation, whereas addition of sulfated glycosphingolipids increased the extent of platelet aggregation in ex vivo activated platelets. Similarly, Santoro demonstrated the inhibitory effect of exogenously added gangliosides on platelet adhesion to fibronectin, fibrinogen, and VWF and discovered that the inhibitory effect varied with the number of sialic acid residues expressed by the added gangliosides. These results suggest that platelet function may be modulated by gangliosides and their post-translational modifications. Although further mechanistic and clinical studies are required, overall these data support the concept of a functional role for the dynamic and regulated expression of specific glycosphingolipids during platelet activation and in arterial thrombosis.

Like platelet glycoproteins, ABH antigenicity is also expressed on platelet surface glycolipids. Cooling et al demonstrated that neutral glycosphingolipids, hexosylceramide (A6), and octaosylceramide (A8) express A antigenicity in type A platelets, whereas no ABH antigenicity was identified on type O platelets. Similarly, 5 acidic glycosphingolipids were identified that also express A antigenicity on type A platelets. Although the exact structures of the 5 acidic glycosphingolipids could not be identified, it is thought that they are likely monosialo, long-chain gangliosides, unlike the complex, branched glycosphingolipids that express ABH antigenicity on RBCs. Similarly, glycosphingolipids expressing B antigenicity have been identified on type B platelets. The role and impact of ABO on glycosphingolipid functions in platelets, however, remain uncertain particularly because published work suggests that only a small proportion (estimated at <1%) of all known platelet glycosphingolipids and gangliosides may carry ABH antigens. Although limited in quantity, these post-translational modifications of glycosphingolipids may have important effects on platelet function.

Variability in ABO Expression on Platelets

The degree of ABH antigenic expression on platelet glycoproteins and glycolipids varies not only across ABO blood groups but also within individuals of the same blood group. Hou et al demonstrated that blood group A and B antigens are heavily associated with glycoprotein Ib and glycoprotein IIb, with glycoprotein IIb being the most prominent. However, there were differences in antigenic expression, even within a specific blood group phenotype. For example, blood group A is characterized by 2 specific subgroups, A1 and A2, where the A2 genotype represents a mutation involving single base deletion, which ultimately results in an A2 glycosyltransferase with 30- to 50-fold less activity than A1. In examining these subgroups, platelets with the A2 polymorphism do not express A antigens on glycoproteins Ib and IIb and expressed only one tenth the amount of antigen on glycolipids as individual with A1 platelets.

Several studies have found that a subset of A and B individuals express significantly more A and B antigens on their platelet surfaces than the general population and are termed high expressers. Roughly 7% of type A individuals and 4% to 7% of type B individuals are high expressers for A and B antigen expression, with higher levels of A and B antigens expressed on glycoprotein Ib/IX, Ia/IIa, IV, PECAM, IIb/IIIa. While examining type A individuals, Curtis et al used flow cytometry to discover that individuals with an A2 polymorphism have undetectable or barely detectable levels of A antigen, whereas individuals with an A1 polymorphism express low levels of A antigen. Yet, ≈7% of A1 individuals and 4% of B individuals expressed A and B antigens levels >2 SDs above the mean, with higher levels of antigens on various platelet glycoproteins, but especially glycoprotein IIb and PECAM. The mechanism behind this differential expression may lie in differences in enzymatic activity, as well as in H antigen abundance and modification; high expressers concomitantly show higher levels of A1 and B glycosyltransferase activity and lower levels of H antigen on their red blood cells.

Subsequent studies further examined the determinants of this differential expression of ABH antigenicity within blood groups. Cooling et al studied 131 type A platelet donors, where similar to previous studies, antigen was expressed on platelet membranes, glycoproteins, and glycosphingolipids of A1 platelets. ABH antigen expression varied significantly between donors, but did not vary significantly over time within donors. Expression was influenced by specific A subtype, age, and sex, with the A1 versus A2 subtypes being the greatest predictor of platelet ABH antigen expression. Concordance was shown between A1 phenotype and A antigen expression on platelet membranes, glycoproteins, and glycosphingolipids. Among the A1 phenotype, there was
a linear coexpression of A and H antigens, suggesting that platelet ABH antigen expression is also dependent on the abundance of H antigens, and not solely on A and B glycosyltransferase activity. Similarly, blood group B platelets also displayed differences in the expression of B surface antigen. Ogasawara et al demonstrated that 7% of type B individuals were high expressers for B antigen, with increased levels of B glycosyltransferase activity. In these high expressers, glycoprotein IIb and IIa were shown to express the large amount of B antigen on the platelet surface. Clinically, high expressers were found to have rapid clearance of ABH mismatched platelet transfusions.

While interesting, the molecular basis and clinical significance of high ABH expression, beyond implications in transfusion medicine, are still being investigated. However, there is already evidence that the level of platelet ABH expression can vary depending on platelet activation and storage conditions, either through granule translocation or changes in glycosyltransferase activity. Therefore, one hypothesis might be that high expression of A or B antigenicity, relative to that of blood group O, influences the risk of coronary thrombosis via the degree of modification of important glycoproteins, such as glycoprotein Ib, glycoprotein IIa, glycoprotein IIb, and PECAM. In addition, the degree and impact of post-translational modification of these platelet glycoproteins may be different at rest and during platelet activation preceding a thrombotic event. Investigating the potential impact of high ABH expression on platelet function at rest and during activation, as well as on other cells involved in arterial thrombosis, such as endothelial cells, may inform diagnostics, through biomarker development and risk prediction and by identifying individuals with atherosclerosis who may be at higher risk for thrombosis and therefore, ACS/MI.

Potential for ABO Modulation of Platelet Function and Arterial Thrombosis
Platelets play a pivotal role in ACS with formation of a platelet aggregate at the site of a ruptured atherosclerotic plaque or locus of endothelial denudation. Platelets adhere to sites of injured vessels via the binding of subendothelial collagen to glycoprotein Ia/IIa and ultimately forming a platelet-rich plug via the binding of VWF or fibrinogen to activated platelet glycoprotein IIb/IIIa, the transmembrane receptor complex that serves as the dominant final common pathway for thrombosis and therefore, ACS/MI. Moeller et al examined 162 healthy donors with normal in vivo bleeding time end points, factor VIII activity, VWF structure, and ristocetin-induced platelet aggregation. In this study, type O individuals demonstrated a longer bleeding time than non–type O individuals (89±14.6 versus 82±13 s; P<0.01), indicating an in vitro effect of ABO blood group on primary hemostasis. Favaloro et al examined 452 donors across blood groups and demonstrated an association between type O group and lower levels of plasma VWF, collagen binding activity and factor VIII coagulant activity. Interestingly, type O individuals also had lower levels of ristocetin cofactor activities, suggesting a higher rate of platelet aggregation to ristocetin in non–type O individuals. However, there was no association between blood group status and the ratio of total VWF:functional VWF. The authors concluded that ABO blood group may influence platelet adhesion via the binding of VWF, conferring increased rates of thrombosis to blood in non–blood group O carriers.

Feuring et al demonstrated that although ABO blood group was associated with differences in measures of ex vivo platelet function, ABO blood group status did not influence the effect of a range of glycoprotein IIb/IIIa receptor antagonists in blocking the receptor and inhibiting platelet function. These studies suggest that ABO affects certain surrogate in vitro measures of platelet function, possibly via glycan modifications of platelet glycoproteins or glycolipids. However, it remains uncertain what effect, if any, platelet ABO glycan modifications have on clinically relevant platelet function and arterial thrombosis in vivo.

Platelet Glycobiology Beyond ABO Modifications
Despite limitations of present knowledge on the extent, specific targets, and function of ABO modification of platelet glycoproteins and glycolipids, ABO glycosylation may prove to be an important model for the role of glycemic pathways in platelet function and ultimately arterial thrombosis. Studies by Wandall et al have shown that platelets contain functional intracellular and surface glycosyltransferases, with the ability to glycosylate exogenously added glycoprotein Ib, IIb, and VWF. Furthermore, although platelets expressed functional glycosyltransferases at rest, they release ≈50% of their glycosyltransferase activity, as well as sugar nucleotides substrates, on activation by thrombin receptor agonist peptide or ADP. These results suggest that platelets contain a complete glycosylation apparatus, which on activation allows platelets to modify surface glycans. In fact, when human platelets were activated in the presence of mouse platelets, sialic acid was noted to be added to mouse platelet surface glycoprotein Ib. To test the effect of modification of surface glycoproteins on platelet function, the bleeding times of sialylated platelets were compared against nonsialylated platelets in vitro. Platelets that incorporated sialic acid into their surface glycoproteins were found to be less responsive, with significantly longer bleeding times than controls.

Post-translational modification of platelet surface glycoproteins can play an important role in determining
platelet-specific alloantigenicity. Bak is a platelet-specific alloantigen expressed on glycoprotein IIb. Take et al64 tested the hypothesis that post-translational sialylation of glycoprotein IIb affected the expression of Bak epitopes. The authors demonstrated that the binding of 4 anti-Bak sera to Bak changed depending on whether neuraminidase was administered to desialylate glycoprotein IIb. A subsequent study by Goldberger et al65 demonstrated changes in electrophoretic mobility and reactivity to antisera when Bak and Bak platelets were exposed to neuraminidase, thereby desialylating glycoprotein IIb. The authors concluded that in addition to a change in amino acid 843 of glycoprotein IIb, from isoleucine to serine, post-translational sialylation of glycoprotein IIb was also necessary for the expression of Bak and Bak epitopes.

From a clinical perspective, Davoren et al66 examined 1162 cases of neonatal alloimmune thrombocytopenia, a disease thought to be mediated by the placental passage of platelet-specific alloantibodies and discovered that alloantibodies to Bak epitopes contributed to 2% of all cases. Other polymorphisms in platelet-specific antigens have also been associated with various disease states, including coronary thrombosis. A study by Weiss et al67 showed a higher prevalence of PI A2 (39.4 versus 19.1%), a polymorphism on another platelet-specific antigen, in patients with a history of MI or unstable angina compared with controls. Therefore, it is possible that post-translational modification, including sialylation, of platelet glycoproteins can impact platelet function via the differential expression of platelet-specific alloantigens.

Although glycans modifications of platelet receptors seem to play a role in platelet function, understanding the exact role of glycan modification of these glycoproteins, including ABO glycosylation, in resting and during activation of platelets may offer new insights into the pathophysiology of thrombosis and provide opportunities for diagnostic and prognostic translations and for novel therapeutics.

Systematic Glycomic Profiling of Platelets

Over the years, many studies have shown that ABO groups are associated with ACS and thrombosis, and that ABH antigens are expressed on platelet surface glycoproteins and glycolipids. However, the specific glycans, glycopeptides, and glycolipids on platelets, modified by ABO glycans, and the manner in which these molecules influence platelet function is still largely unknown. Importantly, work by Wang et al68 has shown that specific glycan modifications do indeed play an important role in platelet function. Using mice with targeted deletion of Cosmc, an essential chaperone in O-glycosylation regulation, the authors showed increased incidence of hemorrhage and longer bleeding times, as well as decreased glycoprotein Ib–IX–V and glycoprotein IIb/IIIa function. These findings imply that disruption of O-glycosylation leads to impaired platelet adhesion and clotting via changes in platelet glycoprotein function.

Mass spectrometry and glycan binding lectins can provide additional insights into platelet-specific glycomic modifications by providing information on changes in structure, content, and configuration of specific platelet glycoproteins and glycolipids.69 A recent study by Mercado et al70 used mass spectrometry to probe the mechanism in which elevated plasma levels of serotonin accelerate platelet aggregation. This study revealed modification of the content of N-glycans on mouse platelet surfaces after infusion of serotonin, with a switch in the N-glycan structures on platelet glycoproteins from predominantly N-acetyl-neuraminic acid to N-glycolyl-neuraminic acid. The authors postulated that these glycoprotein modifications underlie the mechanism by which serotonin enhances platelet aggregation.

To further explore the role of ABO groups in modifying platelet function, the complete extent of N-, O-, and glycosphingolipid species and targets in platelets at rest and during activation will need to be defined in an unbiased manner. Although mass spectrometry has been used to highlight specific proteins in the platelet sheddome71 and within platelet microparticles,72 fractions that contain key local and systemic signals modulating thrombosis in clinical disease, a complete analysis of all glycoprotein and glycosphingolipid species is lacking. In the context of ABO, a combination of unbiased proteomics, emerging glycoproteomics, and lectin arrays targeting ABO pathways may be used to uncover which specific
peptides carry modifications. Such deep and complete profiling of glycoproteins and glycosphingolipids will allow determination of the presence, abundance, and targets of ABO and other glycan modifications in platelets, providing opportunities for clinical translation.

Furthermore, it may be useful to consider ABO as a model for the broader impact of post-translational glycan modification on platelet function. Therefore, deep glycopeptide and glycoproteomic interrogations are required to identify which proteins carry specific modifications and at which residues and domains. Such unbiased profiling will uncover many potentially biological and clinically important glycoprotein modifications, not just those of ABH antigenicity. These modifications can be studied further, through mutagenesis in vitro and in vivo, for their impact on the function of these proteins, and in vivo for their related platelet activities in thrombosis and vascular disease. Such discovery and follow-up functional analyses will help define the effect of established ABO modifications on glycoproteins, such as glycoprotein Ia, glycoprotein Ib, and glycoprotein Ib/IIa, as well as discover novel, and perhaps platelet-specific, glycopeptides, and glycoproteins, that modulate platelet function and arterial thrombosis. Although ABO expression on platelet surface glycoproteins and glycosphingolipids may be of low relative abundance, these may have important functional consequences, whether via terminal modifications of glycoproteins or glycan modifications of glycolipids that are key signaling molecules in platelet-driven thrombosis at sites of atherosclerotic plaque rupture. Future targeted work will elucidate whether glycomic modifications, including ABH glycans, act on platelet functions via specific proteins and lipids or whether there is a more generalized effect of global carbohydrate type and abundance in altering platelet functions.

Conclusions
A growing body of evidence has demonstrated a strong and reproducible association between ABO blood group status and ACS, whereby non-type O blood group, compared with blood group O carriers, is associated with increased risk of CVD. Although the exact mechanism of this effect is largely unknown, several glycoproteins and glycosphingolipids on the surface of platelets are known to express ABH antigenicity. It is hypothesized that ABO modification of these glycans may affect platelet function and thrombosis. Additional studies are needed to thoroughly investigate the presence, targets, and extent of these ABO modifications and how they modulate platelet function in arterial thrombosis. A better understanding of all types of glycomic modifications and their potential impact on platelet function and thrombosis may impact future diagnostic and therapeutic targets in ACS and CVD.

Several studies have demonstrated a relationship between ABO blood group and acute coronary syndromes, where O blood group has been associated with lower rates of incidence, infarct size, and mortality. Research into this relationship has focused primarily on the impact of ABO blood group on circulating von Willebrand Factor and integrins. However, platelets play a pivotal role in arterial thrombosis. Therefore, our review focuses on ABO blood type from a platelet perspective. We review the expression of ABH antigens on platelet glycoproteins and glycosphingolipids and highlight studies that examine the effect of ABO blood group on several platelet function assays. We conclude by providing perspective on future studies that can further elucidate the impact of ABO glycans modification on platelet aggregation and function. Understanding the effect of ABO blood group on platelets highlights the importance of platelet glycoprotein modifications in thrombosis, which may help inform future diagnostic and therapeutic targets.
ABO Blood Group as a Model for Platelet Glycan Modification in Arterial Thrombosis
