Role of Computed Tomography for Diagnosis and Risk Stratification of Patients With Suspected or Known Coronary Artery Disease

Dan K. Kalra, Ran Heo, Valentina Valenti, Ryo Nakazato, James K. Min

Abstract—Cardiac computed tomographic angiography (CCTA) has emerged as a powerful imaging modality for the detection and prognostication of individuals with suspected coronary artery disease. Because calcification of coronary plaque occurs in proportion to the total atheroma volume, the initial diagnostic potential of CCTA focused on the identification and quantification of coronary calcium in low- to intermediate-risk individuals, a finding that tracks precisely with the risk of incident adverse clinical events. Beyond noncontrast detection of coronary calcium, CCTA using iodinated contrast yields incremental information about the degree and distribution of coronary plaques and stenosis, as well as vessel wall morphology and atherosclerotic plaque features. This additive information offers the promise of CCTA to provide a more comprehensive view of total atherosclerotic burden because it relates to myocardial ischemia and future adverse clinical events. Furthermore, emerging data suggest the prognostic and diagnostic importance of stenosis severity detection and atherosclerotic plaque features described by CCTA including positive remodeling, low-attenuation plaque, and spotty calcification, which have been associated with the vulnerability of plaque. We report a summary of the evidence supporting the role of CCTA in the detection of subclinical and clinical coronary artery disease in both asymptomatic and symptomatic patients and discuss the potential of CCTA to augment the identification of at-risk individuals. CCTA and coronary artery calcium scoring offer the ability to improve risk stratification, discrimination, and reclassification of the risk in patients with suspected coronary artery disease and to noninvasively determine the measures of stenosis severity and atherosclerotic plaque features. (Arterioscler Thromb Vasc Biol. 2014;34:00-00.)

Key Words: coronary artery disease

Coronary atherosclerosis is a complex inflammatory process that involves, in part, endothelial damage, deposition of oxidized low-density lipoprotein into the intima, smooth muscle cell proliferation, and macrophage infiltration and activation. Several inflammatory mediators and chemokines contribute to plaque initiation, growth, and rupture, which is the most common proximate event behind sudden coronary thrombotic events that result in acute coronary syndrome. Among the plaque constituents, coronary calcium fares prominently and is virtually pathognomonic for atherosclerosis. Calcium phosphate in a hydroxyapatite form accumulates in intimal atherosclerotic lesions. Calcification of atherosclerotic plaque first appears in the lipid core of the atheroma, juxtaposed to inflammatory cells and occurs by an active process resembling bone formation, under the control of complex enzymatic and cellular pathways. This formation involves osteoblast-like cells, cytokines, transcription factors, and bone morphogenetic proteins (such as bone morphogenetic protein 2A, osteoprotegerin, osteopontin, osteocalcin, and osteonectin) and is characterized by inflammation, lipoprotein and phospholipid accumulation, apoptosis, and finally hydroxyapatite deposition. The inciting mechanisms are not definitively understood, but apoptosis of smooth muscle cells seems to be an important step, which then serves as a nidus for calcification. There is a linear relationship between coronary calcification and total coronary plaque burden on a segmental and entire coronary vessel basis. Based on histomorphometric studies, ≈ 20% of atherosclerotic plaque burden in the coronary vascular bed is calcified, and these macrocalcifications can be identified by noncontrast-enhanced computed tomography (CT).

Methods of Measurement of Coronary Artery Calcium

The identification and quantification of coronary artery calcium (CAC) by CT was first performed using electron beam CT, a technology that provides the high temporal resolution needed to image the perpetually moving coronary arteries. This temporal resolution is facilitated by a CT scanner with a nonmoving gantry using an electron beam steered...
electromagnetically onto tungsten rings to produce x-rays, which are then swept across the patient’s heart and detected on 2 parallel static detector rings. With the recent introduction of multidetector row CT, however, electron beam CT has been generally supplanted by a scanner with superior spatial resolution. By either method, the radiation dose to detect and quantify coronary calcification is low. Radiation exposure of CAC scoring (CACS) is \( \approx 1 \text{ mSv} \), which is comparable with that of a screening mammogram (0.7 mSv). With rapidly occurring further improvements in scanner hardware and software, radiation exposure will go down even further, to <0.5 mSv.

An array of scores has been used to quantify coronary calcium content, among which the Agatston score remains the most commonly used. In this method, calcified lesions above a threshold value of 130 Hounsfield units (HU) and area >1 mm\(^2\) (3 adjacent pixels) are detected based on their density and area. The area of calcification in each of the slices is calculated and multiplied by a weighting factor (eg, for 130–200 HU, a factor of 1 is assigned; for 201–300 HU, a factor of 2 is assigned; for 301–400 HU, a factor of 3 is assigned; and so on). All axial scores are then summed (Figure 2). One caveat is that the Agatston score is prone to overestimation of coronary calcium content, because it is susceptible to partial volume effects, motion, arrhythmias, image noise, and artifacts from metallic clips and implanted defibrillator leads.

To overcome these limitations, Callister et al proposed a volume score because the Agatston score does not take into account the depth of calcium, but rather the area only. Thus, an increase in the Agatston score over time may occur from an increase in the amount of plaque, but may also occur as a result of increased plaque attenuation (density) rather than a true increase in plaque size. In contrast, the calcium volume score is independent of image overlap and slice thickness. In the Multi-Ethnic Study of Atherosclerosis (MESA) study, each participant underwent an electron beam CT and multidetector row CT 2 minutes apart; volume scores showed better reproducibility compared with Agatston scores. A third method of measuring coronary calcium content is the mass score, a technique that multiplies the lesion volume, the

Figure 1. Diagram depicting the progression of coronary atherosclerosis with age. By the teenage years, there is almost universal appearance of type 3 lesions in the aorta. With increasing number of risk factors and age and ensuing endothelial damage, there is progressive growth in atheroma size. Calcification occurs in some of these lesions and leads to increasing calcium deposition with time, which is readily appreciated by noncontrast cardiac computed tomography. CAC indicates coronary artery calcium.
average CT density, and a calibration factor. The method of CACS requires an external standard calibration phantom, but is the most reproducible value because it is independent of hardware or scanning protocols. Nonetheless, these newer scores have a smaller prognostic evidence base of studies, and despite its aforementioned limitations, the Agatston score has been studied extensively for risk assessment in various large population-based studies and continues to enjoy the greatest popularity of use.

### Risk Stratification, Discrimination, and Reclassification of At-Risk Individuals Based on Coronary Artery Calcium Prevalence and Extent

An online arterial age calculator (www.mesa.nhlbi.org) is available to estimate the percentile ranking of a patient compared with the MESA data after taking into account age, sex, ethnicity, and smoking status. This method, although often clinically used, does not effectively identify at-risk individuals. Indeed, an absolute value of CACS of >300 or 400 is more predictive of major adverse cardiac event (MACE) rather than a percentile score. This is especially true in younger patients where the percentile score informs relative risk, whereas the absolute score gives the lifetime risk. CACS increases with increasing age and male sex. In general, CACS in women lag behind men by ≈10 years. The prognostic value of CACS is retained in elderly patients.

Furthermore, the pattern of coronary artery calcification is also important, with greater risk of adverse clinical events occurring in the setting of greater numbers of calcified plaques and more coronary vessels involved, particularly if the calcification is in more proximal segments. A newly developed calcium coverage score incorporates the distribution and dispersion of calcium throughout the coronary tree. In a recent analysis of the MESA database with 3398 patients followed for a median of 7.6 years, the calcium volume score was associated with MACE, but calcium density was inversely associated with MACE, and it is feasible that more calcium-dense plaques might be protective because of a decrease in vulnerability. At this time, there are no data showing that preventive treatment of patients with high CACS is associated with improved cardiovascular outcomes, although it is likely that it does so and that such demonstration will require a large trial with a long follow-up period.

An Agatston CACS of 1 to 99 identifies a mild amount of plaque burden, 100 to 399 is moderate, >400 is high, and >1000 is severely elevated. A score of 0 carries an excellent prognosis in asymptomatic patients. Pooled analysis from 6 studies from 2003 to 2005 with 27,622 asymptomatic patients showed that 43% had a CACS of 0 and a low rate of MACE of 0.4% during a 3- to 5-year follow-up. The risk ratio for MACE increased to 7.2-fold for a CACS between 400 and 1000 and to 10.8-fold for a score >1000, therein demonstrating a continuous graded relationship between CACS and MACE. Survival rates have also been shown to have a similar graded relationship: from a large observational study of 25,253 patients with a mean follow-up of 6.8±3 years, cumulative 10-year survival was 99.4% for a CACS of 0, which dropped to 87.8% for a score >1000. In a systematic review of 13 studies with a total of almost 65,000 patients, 45% had a CACS of 0, and their event rate was 0.56% during 4.25 years of follow-up. Longer-term follow-up of ≥12 years showed a mortality rate of only 0.4%. Thus, CACS=0 now allows for an intermediate-term warranty period that is more predictive of salutary outcomes, as compared with other methods of risk stratification, such as a negative stress nuclear perfusion study or carotid intima-media thickness. Importantly, although the noncontrast CACS does not permit direct visualization of coronary stenosis, the probability of coronary stenosis increases as the CACS increases (Figure 3). As an example, Shareghi et al observed that among 3529 asymptomatic subjects of the Framingham Offspring Cohort, a zero CACS,
Role of CACS in Symptomatic Patients With Acute Chest Pain

In symptomatic patients, a CACS=0 portends a favorable prognosis, although in this population the negative CACS may be associated with a small but nonnegligible prevalence of noncalcified plaque, a finding predictive of higher adverse clinical event rates (3.6%).22 Thus, although current National Institute for Health and Clinical Excellence guidelines recommend CACS as the initial workup test in patients with acute chest pain with a low pretest probability,29 this strategy will miss a small proportion of patients whose CACS=0 but, nonetheless, possess high-grade noncalcified plaque. In a series studying these populations, ≈6% to 12% of patients have only noncalcified plaque.30,41 This strategy may be most useful in the low-risk population, as evidenced by a study of 1031 patients with chest pain evaluated in the emergency department, where 61% had a CACS of 0 and were discharged home.42 Of these, only 0.3% had events during 6 months of follow-up. A CACS of 0 was also correlated with a normal, follow-up single-photon emission CT perfusion scan. However, there is the possibility of missing high-grade stenosis from noncalcified plaque by the use of CACS only. Because calcified plaque represents ≥20% of all plaque burden, despite the above reassuring data, there continues to be some controversy whether a CACS of 0 can be used to make discharge decisions in patients with acute chest pain.

Germance to these findings, the sensitivity and specificity for a CACS >0 for predicting any stenosis ≥50% is 91% and 49%, respectively. However, the negative predictive value to exclude high-grade stenosis is high in the setting of a CACS=0, where the probability of ≥50% stenosis is <1%.10 As the CACS increases, the probability of obstructive CAD increases; for example, for a CACS >400, the likelihood of a >50% stenosis is >60% (Figure 3).26
Progression of CACS
In the MESA study, conversion from a CACS=0 occurred annually in 5% of 50-year-olds and in >12% of 80-year-olds. In those patients, CAC progression was associated with 1.5-fold increased risk of hard CHD events. Among patients with CAC at baseline, event risk was 6-fold higher when the progression rate was >300 units per year.53 CAC progression rates were associated with conventional CHD risk factors, such as age, male sex,46 smoking,63 hypertension, fasting plasma glucose,66,67 family history of premature CAD,46 and diabetes mellitus.50,55 Novel markers of risk for CHD were also investigated. Although microalbuminuria,51 carotid intima-media thickness,52 white race,53 and polymorphisms of the renin–angiotensin system genes51 predict progression of subclinical coronary atherosclerosis, the C-reactive protein did not.54,55 Interestingly, although abdominal obesity,56 body mass index,57 and metabolic syndrome56 were associated with the progression of CACS, the levels of low- and high-density lipoproteins were related just with the incidence and not with the progression of preclinical atherosclerosis disease.43

It has been described in a community-based screening cohort that calcium screening led to a 3- to 7-fold increase in the use of aspirin, statins, and lifestyle changes over 6 years.58,59 However, data on the effect of lipid-lowering therapy on the rate of progression of CACS has been still conflicting. Previous studies described positive correlation between statin treatment, serum lipid levels, and coronary calcium progression.13,60–62 More recently, however, several studies demonstrated that statin treatment was not able to reduce the progression of CACS,63–66 independently from the serum level reduction of cholesterol and low-density lipoprotein.63,64 St Francis Heart Study is the largest prospective trial evaluating lipid-lowering therapy on CAC progression.66 It randomized 1005 patients with CAC equal to or greater than the 90th percentile for age and sex to statin treatment (20 mg atorvastatin daily) versus placebo and followed them prospectively with a repeat CACS in 4.3 years. Although it demonstrated a reduction in the low-density lipoprotein by 43% from baseline (146 mg/dL), the CACS increased from 528 to 846, and the 3% absolute risk reduction in the composite MACE end point in treated patients versus placebo did not reach statistical significance (P=0.08; trend toward significance). Remarkably, in the subgroup of patients with a baseline CACS >400 (almost half of the study population), MACE was reduced by 42% (P=0.046). This discrepancy between CACS progression and MACE reduction may be explained on the basis of plaque stabilization by statins that involves depletion of lipid core and reduction in plaque macrophage content and inducing a fibrovascular transformation of thin-cap fibroatheroma (TCFA).3 Thus, although the plaque may become less vulnerable and the plaque volume may regress, the relative proportion of calcium may actually increase, accounting for these observations.

A continued increase of CAC may indicate inefficacy of the lipid-lowering therapy, and a rapid increase in the score is associated with incident myocardial infarction70,71 beyond conventional cardiovascular risk factors and current algorithm models for CHD risk prediction.64 Conversely, those with baselines scores <100 and progression <15% are at lower risk.57 In a study of 422 patients, the highest rate of conversion from a CACS=0 was in the fifth year and was nonlinear (ie, 15% cumulative in the first 4 years and 25% in the fifth year), suggesting that 4 years might be the warranty period for a CACS=0, a period longer than the 2-year warranty period that is generally espoused for a normal stress perfusion study.45 However, at this time, repeat CACS testing is considered inappropriate for general use because of lack of data from large-scale randomized trials showing that this strategy reduces adverse events.64

Extracoronary Calcium
Cardiac CT angiography (CCTA) is also able to identify noncoronary calcification. One example of this is mitral annular calcification (MAC), which has been shown to increase the risk of MACE. MAC increases with age and hypertension and is more common in women.66 On transthoracic echocardiography, the prevalence of MAC in women aged >65 years without evident cardiovascular disease is as high as 40%.67,68 MAC is also correlated with CACS,58,69 CAD,71 and vulnerable plaque72 and increases the risk of MACE.73 Other cardiac and vascular foci of calcification such as aortic valve calcification, intramyocardial calcification in healed infarct scars, and thoracic aortic calcium also provide additional risk information. However, in a recent analysis from the MESA trial, the addition of thoracic aortic calcium, aortic valve calcification, or MAC to the FRS did not improve cardiovascular risk prediction, and that CACS alone was the strongest factor to predict incident adverse events.80

Plaque Characterization
Because CACS does not detect noncalcified plaques, contrast-enhanced CCTA is more ideally suited for noninvasive detection of noncalcified components of coronary atherosclerotic plaques and in the classification of plaques along the spectrum of stable to vulnerable.75–79 Current CT scanners are capable of visualizing not only the lumen for coronary stenosis assessment but also the vessel wall and providing information on plaque size, length, volume, geometry, composition, and adverse features. CCTA has shown its ability to effectively rule out obstructive and nonobstructive CAD with an exceptionally high negative predictive value, a finding associated with low incident MACE rates.80,81 CT harnesses the different tissue attenuation values of different plaque components, such as fibrous tissue, lipid core, and calcium, to characterize plaque as calcified plaque, noncalcified plaque (NCP), and mixed plaque (Figure 4).82

Qualitative plaque measurements such as calcified plaque, NCP, and mixed plaque have been demonstrated to be consistent among readers, with good intra- and interobserver agreement (r>0.8).83–87 These 3 plaque types by CCTA have different compositions when validated against virtual histology intravascular ultrasound (IVUS) and may be able to effectively differentiate the risk state of specific plaque types. As an example, 32% of mixed plaques in a recent study were associated with TCFA.88 In a recent meta-analysis of 20 studies, CCTA had excellent accuracy in detecting plaque (AUC, 0.94; sensitivity, 90%; specificity, 92%).86 Plaque area, volume, and...
percent area stenosis on CCTA were similar to IVUS.\textsuperscript{89} CCTA demonstrated slight overestimation of lumen area compared with IVUS by 0.46 mm\(^2\) (6.7%), likely because of partial volume effects from the contrast-filled lumen. Plaques with >10% necrotic core on virtual histology IVUS had lower attenuation values by CT versus those that did not (43 versus 93 HU).\textsuperscript{84,90} Otsuka et al\textsuperscript{91} reported that CCTA overestimated calcified plaque volume by only 3% but underestimated NCP by 17%. Voros et al\textsuperscript{84–86} showed that lumen area was overestimated by 22% on 64-slice CT compared with IVUS. Similarly, vessel area, NCP area, and calcified plaque area were also overestimated by 19%, 44%, and 88%, respectively. NCP by CCTA correlated best with necrotic core plus fibrofatty tissue.

CCTA is also reproducible for the quantification of arterial luminal diameter and area, plaque size, volume, geometry, and features. Although there remains some variability at smaller plaque volumes (\(\approx 10 \text{ mm}^3\)) because of the limited spatial and temporal resolution of present-generation CT, CCTA measurements are robust with larger plaque volumes (\(\approx 100 \text{ mm}^3\)).\textsuperscript{82} Our group reported on the interobserver variability of plaque quantification measures, demonstrating good correlation between different observers.\textsuperscript{93,94} To further improve the reliability of measurements and make them less time-consuming, standardized automated software is capable of reducing interobserver variability and improving the limits of agreement.\textsuperscript{87} CT generally overestimates the minimum lumen area by 27%, but area stenosis is only underestimated by 5%.\textsuperscript{96}

In a comparison of CCTA with optical coherence tomography, Kashiwagi et al\textsuperscript{95} observed several indices of plaque instability by CCTA to be associated with TCFAs, including increased remodeling indices in TCFAs (1.14 versus 1.02) and lower attenuation values (35 versus 62 HU). In addition, ring-like enhancement (also referred to as a napkin-ring sign), characterized by contrast accumulation in the periphery of the plaque but not in the central core, is observed in 44% of plaques with TCFA versus only 4% in plaques without TCFA. As opposed to these technologies (IVUS and optical coherence tomography), which allow morphological assessment, near-infrared spectroscopy uses the infrared light absorption spectrum of cholesterol to identify the cholesterol content of plaques in the artery. CCTA has shown good correlation of plaque features compared with this newer technology also. Voros et al\textsuperscript{84} demonstrated good spatial correlation between cholesterol localization on the block chemogram on near-infrared spectroscopy and the presence of NCP as well as the plaque burden on CCTA. The advantage of CCTA is that it is noninvasive and lends itself to serial follow-up to assess changes in plaque geometry and composition as compared with the other 3 invasive modalities.\textsuperscript{96}

**Prognosis**

Given the relationship of CCTA artery and plaque features with measures of plaque stability, an abundance of recent data has examined the prognostic use of CCTA-identified stenosis and plaque constituents. In a recent meta-analysis of 18 studies with 9592 patients with suspected CAD, CCTA robustly predicted MACE as well as all-cause mortality during a median follow-up of 20 months.\textsuperscript{97} When stratified according to tertiles of no stenosis versus <50% stenosis and >50% stenosis, the annualized rates of MACE were 0.17% versus 1.4% versus 8.8%. Rates for all-cause mortality were 0.15% versus 0.75% versus 2.2%. Further similar results have been reported for MACE in a large, prospective, multinational, multicenter Coronary CT Angiography Evaluation for Clinical Outcomes: An International Multicenter (CONFIRM) study of 15 187 patients without previous known CAD.\textsuperscript{98} Among these patients, 595 MACEs (3.9%) occurred at 2.4±1.2 years of follow-up. In multivariable analyses, an increased risk of MACE was observed for both nonobstructive (hazard ratio [HR], 2.43; \(P<0.001\)) and obstructive CAD (HR, 11.21; \(P<0.001\)) when compared with patients with normal CCTA. Risk-adjusted MACE increased in a dose–response relationship based on the number of vessels with obstructive CAD \(\geq 50\%\), with increasing hazards observed for nonobstructive (HR, 2.54; \(P<0.001\)), obstructive 1-vessel (HR, 9.15; \(P<0.001\)), 2-vessel (HR, 15.00; \(P<0.001\)), or 3-vessel or left main (HR, 24.53; \(P<0.001\)) CAD. Among patients stratified

![Figure 4. Examples of different patients with the 3 different major plaque types based on computed tomographic angiography appearance and attenuation values. A, Noncalcified plaque. B, Mixed plaque, which consists of calcific lesions interspersed within noncalcific lesions. C, Calcified plaque, wherein most of the plaque is calcified.\textsuperscript{82}](http://ab休假journal组织.org/ by guest on April 20, 2017)
by age <65 years versus ≥65 years, older individuals experienced higher risk-adjusted hazards for MACE for nonobstructive, 1-, and 2-vessel, with similar event rates for 3-vessel or left main (P<0.001 for all) compared with normal individuals aged <65 years.

Our group has also examined the prognosis of CCTA luminal stenosis by a modified Duke CAD index, which integrates not only stenosis severity but also the distribution and location of plaque.82 Using this measure, stenosis findings by CCTA offer improved risk stratification. Survival worsens with higher Duke score (96% survival for 1 stenosis >70% dropping to 85% survival for left main stenosis >50%).

Measures of stenosis severity as a function of prognosis transcend conventional definitions of anatomically severe. Lin et al99 studied the presence and extent of nonobstructive CAD and showed that the presence of any plaque increased the risk of death beyond clinical risk factors (Figure 5).99 Hazard ratios for all-cause mortality over 3 years in this study increased from 1.98 for the presence of any plaque to 5.12 when >5 segments were involved with nonobstructive plaque.

In addition to measures of stenosis severity, CCTA offers prognostic power by atherosclerotic plaque features. As an example, culprit lesions at the time of acute coronary syndrome demonstrate higher plaque volume, remodeling indices, larger vessel areas, less overall calcification, more low-attenuation plaques (<30 HU), spotty calcifications, and ring-like enhancement patterns.100–104 In a prospective study of 1059 patients undergoing CCTA for the evaluation of chest pain, 4% of patients possessed plaques with both low-attenuation plaque and spotty calcification. Among this subset, 22% developed acute coronary syndrome at 27 months of follow-up.105 In contrast, only 0.5% of patients without either of these 2 features developed acute coronary syndrome, providing preliminary evidence that these atherosclerotic plaque features are infrequently seen in stable outpatients, but if seen can portend a worse downstream event rate.

CCTA offers prognostic value beyond that of CAC.106 This is true even in patients with a zero CACS.26 Furthermore, the burden of atherosclerotic involvement by CCTA correlates well with mortality and cardiac event rate. The worst prognosis is observed in left main and in 3-vessel coronary disease, and then there is a graded decrease in risk with proximal left anterior descending artery disease and further lower risk with 1-vessel disease.82 Nonetheless, even patients with nonobstructive disease (<50%) fare worse compared with those with normal CTAs, indicating that the total plaque burden bears a close relationship to cardiac event rate and prognosis.99 The segment involvement score and segment stenosis score and Duke CT jeopardy score are 3 different ways of quantifying the degree of atheroma burden and stenosis, respectively, in the entire coronary arterial tree.

CONFIRM is a 27,000-patient international CCTA registry involving 12 centers in 6 countries that is tracking patients who underwent a clinically indicated CTA between 2005 and 2009 and following them prospectively for cardiac events.107 It has yielded a wealth of information about the relationships and interactions between risk factors and scoring systems (including FRS), lipid levels, and the extent and distribution of plaques as well as clinical events. Given its unparalleled large patient cohort size and prospective design with cumulative follow-up, it exists as a robust database to evaluate the relationships between various aspects of CAD, including sex, lipids, treatment patterns, and prognosis. Its limitations are that it is not a randomized comparison but rather an observational registry and is, therefore, subject to referral and treatment biases.

Serial Progression

Data on serial coronary plaque progression evaluation by CCTA are scant, but general thematic lessons are emerging. Early studies have determined that <1 to 2 years there is an observable increase in plaque volume and extent by CCTA. In a single-center study of 50 patients followed for 17 months who were not treated with medical therapy for CAD, noncalcified plaque volume in the left main and proximal left anterior descending artery increased from 91 to 115 mm³.108 In contrast, in a separate study of patients on statin therapy, no significant changes in overall plaque volume were observed at 18 months. These neutral findings were nevertheless accompanied by a decrease in the noncalcified portion of the plaque from 42 to 30 mm³.109 Concordant with this study is another investigation that comprised patients without any specific

Figure 5. Presence of nonobstructive coronary artery disease is associated with poorer survival compared with patients who have no visible plaque on coronary computed tomographic angiography. In this study of 2583 patients, the presence of any nonobstructive plaque carried a 1.98-fold higher risk of death at 3.1 y; compared with the group without any plaque. This risk increased further if more vessels were involved; when all 3 major epicardial coronaries showed nonobstructive plaque, the hazard ratio for death increased to 4.75, after adjustment for coronary artery disease risk factors.20
intervention to assess the natural history of plaque progression, demonstrating an increase in noncalcified plaque from 27% at baseline to 35% at 1 year of follow-up, with a decrease in minimum luminal area.87 This study advances the notion that the percent atheroma volume may be a better parameter to evaluate changes in plaque volume over time relative to the extent of arterial remodeling and may be a useful adjunct to conventional measures of luminal stenosis severity.

Role of CCTA in Symptomatic Patients With Acute Chest Pain

In patients presenting to the emergency department with acute chest pain, the evidence for CCTA has grown rapidly and now includes 4 randomized trials that have convincingly shown that a negative CCTA is associated with a low cardiac event rate, shorter length of stay, and lower rates of hospital admission as well as cost savings (Goldstein et al.110 Coronary Computed Tomography for Systematic Triage of Acute Chest Pain Patients to Treatment [CT-STAT].111 American College of Radiology Imaging Network [ACRIN].112 Rule Out Myocardial Infarction by Cardiac Computed Tomography [ROMICAT] II).113 As such, CCTA allows busy hospital emergency departments to safely discharge such patients as opposed to the conventional strategy of admitting these patients for a rule-out myocardial infarction protocol followed by stress testing, all while decreasing resource utilization and improving efficiency. Given these data, the appropriate use criteria now classify CCTA as an appropriate test for such patients who have a low to intermediate pretest probability of having CAD.114

Future Developments in CT

The recently completed HeartFlow Analysis of Coronary Blood Flow Using CT Angiography: Next Steps (HeartFlow NXT) trial115 enrolled 254 patients and demonstrated the potential of fractional flow reserve derived from CT angiography (FFR_{CT}) to correctly identify patients with ischemia better than a purely anatomy-based evaluation. All patients underwent CTA, FFR_{CT} invasive angiography, and also invasive FFR as the gold standard. FFR_{CT} had a specificity of 79% to rule out ischemia compared with 34% for CTA and 54% for internal carotid artery. Sensitivity to detect ischemia was 86%. Similar to the Determination of Fractional Flow Reserve by Anatomic Computed Tomographic Angiography (DeFACTO) trial, the AUC for FFR_{CT} was =20% better at 0.82 versus 0.63 for CCTA, signifying the ability of FFR_{CT} to better discriminate lesion-specific ischemia. A strategy of revascularization based on FFR evaluation has been shown to decrease cardiac event rate, mortality, and reduce costs by =$3000 per patient.116–118 Other advantages of FFR_{CT} are that it does not require additional contrast and that analysis can be performed on the same data set as acquired during the CCTA without any additional modification of the scanning protocol.

Summary

In recent years, CT has emerged as a robust technology with demonstrable utility in the evaluation of asymptomatic and symptomatic patients with suspected CAD. A plethora of population-based studies has confirmed the usefulness of CACS to offer improved risk stratification, discrimination, and reclassification compared with conventional risk assessment of CAD. CCTA has been introduced as a more contemporary adjunct to CACS, offering the ability to determine measures of stenosis severity and atherosclerotic plaque features. In large-scale studies, these findings may enable improved risk stratification than even CACS and may hone the ability to identify individuals at risk of incident myocardial infarction or death.
